B. Pelletier[21] reported a **molybdenum phosphide** to be formed by the action of phosphorus vapour on molybdenum, but he did not examine the product further. F. Wöhler represented its formula by MoP, and obtained it by heating a mixture of molybdenum trioxide, and phosphoric acid, in a carbon crucible above 1400° for some hours; and washing the product with hydrochloric acid and soda-lye. The grey, crystalline powder has a sp. gr. 6·167; it fuses with great difficulty; and conducts electricity. In a soln. of cupric sulphate containing zinc and hydrochlroic acid, the phosphide acquires a coating of copper. It slowly oxidizes without burning when heated in air. It also forms molybdenum and phosphorus chlorides when heated in chlorine; hot nitric acid converts it into molybdic and phosphoric acids; and molten potassium nitrate oxidizes it with incandescence. B. Pelletier made the qualitative observation that tungsten heated with phosphorus vapour forms a phosphide, and F. Wöhler represented it as **tungsten hemiphosphide,** W_4P_2, and made it by heating a mixture of tungsten trioxide, and phosphoric acid in a carbon crucible for some hours above 1400°. The lustrous, dark, steel-grey mass contained six-sided prisms of sp. gr. 5·207. The phosphide conducts electricity; it does not change when heated to a high temp.; and oxidizes very slowly when heated to redness in air. It burns when heated on charcoal in oxygen; and with *einem blendenden Glanz* when added to fused potassium chlorate. It is not attacked by any known acid, not even by aqua regia; it is opened up by a fused mixture of potassium carbonate and nitrate; and it behaves like molybdenum phosphide towards a soln. of copper sulphate. According to E. Defacqz, when tungsten diphosphide is heated with copper in the electric furnace, it is decomposed; but if it is heated with a large excess of copper phosphide in a graphite crucible in a wind furnace and the product treated with dil. nitric acid, a new phosphide, **tungsten monophosphide**, WP, is obtained in grey, lustrous, prismatic crystals of sp. gr. 8·5. This compound burns in air or oxygen at a red-heat, and is likewise attacked by chlorine, but it is not decomposed by hydrofluoric or hydrochloric acid, or by hydrogen chloride. It is slowly oxidized by hot nitric acid, and is rapidly dissolved by a mixture of nitric and hydrofluoric acids, or by aqua regia. Sodium and potassium hydroxide soln. have no action on the phosphide, but the fused hydroxides and fused mixtures of alkali carbonates and nitrates readily oxidize it, whilst fused potassium hydrosulphate attacks it slowly. He also prepared tungsten diphosphide, WP_2, by heating tungsten hexachloride at 450° in a current of hydrogen phosphide. This compound is a black, crystalline mass, insoluble in water and the ordinary organic solvents, and having a sp. gr. 5·8. Fluorine attacks the diphosphide at temp. above 100°, forming phosphorous and tungsten fluorides; chlorine and bromine react similarly at a red-heat; when liquid chlorine is employed at 60°, a chlorophosphide is produced. Sulphur and nitrogen both displace the phosphorus from this compound at high temp., forming the disulphide and nitride respectively; the disulphide is also produced by the action of hydrogen sulphide on the phosphide at 500°. The diphosphide readily burns in air or oxygen, forming tungstic and phosphoric oxides, its combustion in the latter gas being attended by a very dazzling flame. A complete reduction of the phosphide is effected by heating it with copper or zinc, tungsten being liberated, and the corresponding metallic phosphide produced; the reduction by hydrogen commences at 525°, but is incomplete even at 900°. Lead at 900° only partially reduces the diphosphide, and copper phosphide at 1400° produces another tungsten phosphide; when heated with iron, the diphosphide is converted into a double **iron tungsten phosphide**; with aluminium, the reaction is even more complicated, and the product contains a large amount of silicon derived from the crucible. Hydrofluoric and hydrochloric acids do not act on the diphosphide, but a mixture of the former with nitric acid dissolves this compound even in the cold, whilst aqua regia decomposes it on warming; sulphuric and nitirc acids, when heated, are reduced by the phosphide, sulphurous acid and blue tungsten oxide being formed in the first case, and nitrous and tungstic acids in the second. The diphosphide is dissolved by fused caustic alkalies and potassium hydrogen sulphate, and is even more readily attacked by heating mixtures of alkali nitrates and carbonates.

The properties of **nitrogen phosphide** are discussed in connection with phosphorus nitride. G. Landgrebe[22] prepared *Phosphorarsen* by heating a mixture of phosphorus and arsenic to dull redness, but J. V. Janowsky regarded the product as a mixture, and he said the same thing about the product of the action of phosphorus vapour on heated arsenic; and the action of sodium or calcium arsenide on phosphorus trichloride. According to C. E. E. Ritter, and N. Blondlot, **arsenic hemiphosphide,** As_2P, is formed slowly when phosphorus is allowed to remain in contact with an aq. soln. of arsenious or arsenic acids, and rapidly if the soln. be acidified with hydrochloric acid. The unchanged phosphorus can be removed by treatment with carbon disulphide. The black mass becomes brown when exposed to air, and it forms arsenic trioxide when kept under water. J. V. Janowsky obtained **arsenic monophosphide,** by the action of dried arsine on phosphorus trichloride below 20°, because at higher temp. some of the arsenic forms a volatile chloride. The excess of trichloride is separated, and the product dried in a current of carbon dioxide at 70°–80°; J. V. Janowsky made it by the action of phosphine on arsenic chloride—A. Cavazzi used a hydrochloric acid soln. of arsenic trioxide. A. Besson found that phosphine begins to react similarly with arsenic trifluoride at —23°; with arsenic trichloride at —18°; while solid arsenic tribromide or triiodide is only superficially attacked, and the tribromide reacts vigorously with phosphine at 20°. If the product of these reactions is washed with water, J. V. Janowsky said that an oxyphosphide is formed, and A. Besson, that impure arsenic phosphite and phosphate are produced. According to J. V. Janowsky, arsenic monophosphide is a reddish powder which burns when heated in air to arsenic trioxide and phosphorus pentoxide; but if heated out of contact with air, or in a current of carbon dioxide, phosphorus first sublimes and then arsenic. Sulphuric and hydrochloric acids dissolve the phosphide only when heated therewith; conc. nitric acid oxidizes it with incandescence, and the dil. acid dissolves it, forming, when heated, arsenic and phosphoric acids; chlorine, bromine, and iodine form the corresponding trihalides of arsenic and phosphorus; potash-lye, aq. ammonia, and baryta-water decompose the phosphide at ordinary temp., and rapidly when heated, forming phosphine, arsine, arsenic, phosphorous acid, and arsenic trioxide. It is slightly soluble in carbon disulphide, but not in alcohol, ether, or chloroform.

According to J. V. Janowsky, if freshly precipitated arsenic phosphide be treated with water, it forms *arsenic dioxydiphosphide*, $As_3P_2O_2$, which decomposes slowly at 100°, and rapidly at 200°. It is not attacked by the ordinary acids other than nitric acid; and it is attacked by alkali-lye, chlorine, bromine, and iodine as in the case of the monophosphide. As indicated above, A. Besson does not agree with J. V. Janowsky on the action of water on arsenic monophosphide. O. Ruff reported *arsenic dioxyphosphide*, As_4PO_2, to be formed by adding red phosphorus to arsenic trichloride containing some aluminium chloride; the red product when treated with water yields the violet-black oxyphosphide.

B. Pelletier[23] obtained an antimony phosphide by the action of molten antimony on metaphosphoric acid with or without admixed carbon. B. Pelletier, and G. Landgrebe obtained a phosphide by the action of phosphorus on molten antimony, although W. Ramsay and R. W. E. McIvor could obtain a product with only 15·46 per cent. by direct action. The last-named prepared **antimony monophosphide,** SbP, by the action of phosphorus on a soln. of antimony tribromide in carbon disulphide. M. Ragg could not prepare the monophosphide by this process, nor by the action of phosphine on tartar emetic, or antimony trichloride. The phosphide prepared by the fusion processes is a brittle, white mass with a crystalline fracture; the precipitated product is a red powder insoluble in carbon disulphide, ether, and benzene. O. Ruff found that phosphorus reacts with antimony chloride in the presence of aluminium chloride—*vide supra*, arsenic oxyphosphide.

B. Pelletier,[24] and C. M. Marx found that molten bismuth dissolves a little phosphorus, and W. Heintz, that when bismuth phosphate is heated in a current of hydrogen, the product may contain some **bismuth phosphide,** but the properties of both products resemble those of a phosphiferous bismuth. J. J. Berzelius, T. von Grotthus, and G. Landgrebe precipitated a black bismuth phosphide by phosphine from a soln. of bismuth nitrate as nearly neutral as possible. The liberated nitric acid decomposes the phosphine so that the yield is small. A. Cavazzi passed phosphine into a soln. of bismuth trichloride with as little free acid as possible, but obtained a black precipitate consisting of bismuth and phosphorus mixed with some oxide and chloride. P. Kulisch said the precipitate may be a mixture of bismuth phosphide and oxychloride, and he obtained no precipitate with a soln. containing 20 grms. of bismuth trioxide in 100 c.c. of hydrochloric acid of sp. gr. 1·124. A. Cavazzi said that when phosphine acts on dry bismuth chloride at 100°, hydrogen chloride is evolved and what is considered to be a bismuth phosphide remains. If phosphine is passed into an ethereal soln. of bismuth trichloride, A. Cavazzi and D. Tivoli observed the formation of a black, hygroscopic deposit with the composition PBi_3Br_7, and considered to be *hydrotrisdibromobismuthphosphonium bromide*, $P(BiBr_2)_3HBr$. When the impure phosphide is heated in a current of carbon dioxide, some phosphorus is volatilized; when heated in air, phosphorus burns with its characteristic flame leaving a white residue of variable composition; when boiled with water, bismuth separates partly as metal, and most of the phosphorus passes into phosphoric acid and a little phosphine; dil. nitric acid freely dissolves the phosphide; dil. sulphuric and hydrochloric acids are without action; conc. hydrochloric acid decomposes it at ordinary temp. with the evolution of non-spontaneously inflammable phosphine; boiling conc. sulphuric acid forms phosphine and sulphur dioxide; and with boiling alkali-lye, bismuth is deposited, and hydrogen, with a little phosphine, evolved.

J. J. Berzelius[25] said that when vanadyl phosphate, mixed with some sugar, is heated, the grey, porous mass which is formed can be pressed together when it has the appearance and lustre of graphite. It is considered to be an impure **vanadium phosphide.**

B. Pelletier[26] prepared a white manganese phosphide by heating manganese with microcosmic salt, and charcoal, or by passing phosphorus vapour over manganese; and H. Rose, J. Percy, and F. Wöhler made a similar alloy by heating calcined pyrolusite with bone-ash, sand, and charcoal. H. Struve prepared what appeared to be a mixture of phosphides by reducing manganese pyrophosphate with carbon; C. Matignon and R. Trannoy obtained a metal rich in phosphides by reducing manganese phosphate by the aluminothermite process; E. Wedekind and T. Veit said that the crystalline product obtained by the thermite process from manganese and red phosphorus is a mixture which is readily attacked by water and dil. acids, and has only feeble magnetic qualities. H. von Jüptner also prepared manganese and manganese phosphide alloys. S. F. Schemtschuschny and N. N. Efremoff determined the f.p. of alloys of manganese with up to 47 per cent. of phosphorus. The alloys were made by melting the metal in a fireclay crucible under fused barium chloride, and adding the phosphorus through a tube made of asbestos. The phosphorus vapour was slowly absorbed by the molten metal. More conc. alloys gave off phosphorus vapour when the attempt was made to work with them. The results are shown in Fig. 24. The two maxima—one at approximately 1390°, and the other at 1190°—correspond with the compounds Mn_5P_2 and MnP; the corresponding eutectics were at 964° and 1095°. Alloys with less than 10 at. per cent. of phosphorus are not magnetic, but with over this quantity the magnetizability rises with increasing proportions of phosphorus up to the appearance of the dipentitaphosphide; after that, the magnetizability becomes perceptibly feebler.

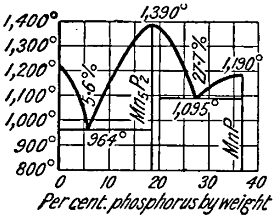

FIG. 24.—Freezing-point Curve of Manganese and Phosphorus.

A. Schrötter prepared an alloy with a composition approximating **manganese tritaphosphide,** Mn_3P, by heating manganese in the vapour of phosphorus at a very dull red-heat; union occurs with incandescence. The sp. gr. of the product is 4·94; it is insoluble in hydrochloric acid, and freely soluble in nitric acid. E. Wedekind and T. Veit prepared **manganese dipentitaphosphide,** Mn_5P_2, when manganese chloride and phosphorus are heated to redness in a current of hydrogen. The conditions of stability are indicated in Fig. 24. It has moderately strong magnetic properties. S. F. Schemtschuschny and N. N. Efremoff gave 1390° for the m.p.; and E. Wedekind and T. Veit reported that the dipentitaphosphide is a dark grey crystalline powder which is stable towards hydrochloric acid or boiling water, but dissolves freely in hot nitric acid. A. Granger reported **manganese ditritaphosphide,** Mn_3P_2, to be formed by heating manganese chloride with phosphorus in an atm. of hydrogen in a sealed tube. The product was washed with water, and small, strongly refracting needles resembling manganite were obtained. E. Wedekind and T. Veit also obtained glistening needles of this phosphide by heating a mixture of manganese and red phosphorus in a current of hydrogen, and finally over the oxyhydrogen flame. They gave 5·12 for the sp. gr. at 18°, and found that it has strong magnetic properties, and when compact is a good electrical conductor. They also said that it dissolves in hot conc. nitric acid, but it is stable towards dil. acids. A. Granger reported that his product was attacked by aqua regia, but not by nitric acid. The phosphide oxidizes slowly when heated in air or oxygen; and it inflames when gently heated in chlorine.

S. Hilpert and T. Dieckmann made **manganese monophosphide,** MnP, by heating the two elements in an evacuated sealed tube at 600° for 10–12 hrs., and then washing the product with 10 per cent. hydrochloric acid. The conditions of stability are indicated in Fig. 24. S. F. Schemtschuschny and N. N. Efremoff gave 1190° for the m.p.; and S. Hilpert and T. Dieckmann found that the monophosphide is an inodorous, black powder of sp. gr. 5·39 at 21°/4°, which burns on heating in air, giving black oxidation products; it is insoluble in hydrochloric acid, but readily soluble in nitric acid. The magnetic properties are lost at 18° on heating, and regained at 26° on cooling. S. Hilpert and T. Dieckmann prepared **manganese diphosphide,** MnP_2. A mixture of manganese (2 grms.) and red phosphorus (2·4 grms.) was heated in an exhausted and sealed Jena-glass tube, first at 400°, and finally at 600°, for a considerable length of time. Any phosphorus unacted on is distilled into the drawn-out end of the tube. The grey contents of the tube, after triturating with benzene, and washing with alcohol and ether, were dried over sulphuric acid in vacuo; they suffered no alteration in weight after heating for 13 hrs. in a current of hydrogen at 290°. When heated at 400°, however, phosphorus was gradually lost, giving, finally, the monophosphide.

The **phosphides of iron** and of copper have been more closely investigated than those of any other element, no doubt because of their industrial importance. About 1780, T. Bergman,[27] and J. K. F. Meyer found iron phosphide in commercial iron, and they regarded it as a peculiar, elemental metal which they designated *siderum*, *Wassereisen*, or *hydrosiderum*; and it was afterwards recognized as a compound of iron and phosphorus by J. K. F. Meyer, M. H. Klaproth, L. N. Vauquelin, and C. W. Scheele. J. K. F. Meyer commenting on his mistake said: To err in chemistry is alas too easy (*Das Irren ist in der Chemie doch, leider! gar zu leicht*). The impure phosphide was made by C. Hatchett by passing the vapour of phosphorus over red-hot iron filings, or by projecting pieces of phosphorus on them; B. Pelletier, by igniting iron filings mixed with phosphoric acid—with or without carbon; F. Wöhler, by heating a mixture of iron filings, bone-ash, quartz-sand, and carbon; J. J. Berzelius, by igniting a mixture of ferrous phosphate and lamp-black—if too much carbon is used, an iron carbide is formed which can be dissolved out by hydrochloric acid with the loss of half the phosphide; and H. Rose, by passing phosphine over gently heated iron pyrites. T. Swann heated iron scrap and phosphate rock in the electric furnace; and E. V. Rawn heated a low-grade ferrophosphorus with a material containing phosphorus, and a flux in an electric furnace.

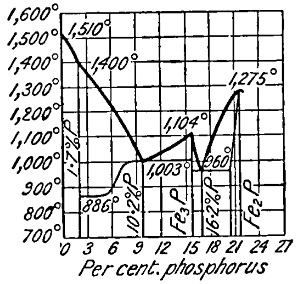

FIG. 25. — Freezing-point Curves of the Fe–P System (B. Sakalatwalla).

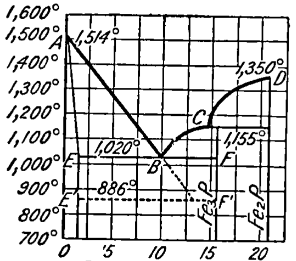

FIG. 26. — Freezing-point Curves of the Fe–P System (N. S. Konstantinoff).

Phosphides ranging from Fe : P=2 : 3 to 6 : 1 have been reported; but, on the f.p. curve for alloys with less than 25 per cent. of phosphorus, only the trita- and hemi-phosphides have been observed. The f.p. curve of a portion of the Fe–P system has been studied by E. Gercke, J. E. Stead, N. S. Konstantinoff, and B. Sakalatwalla. According to J. E. Stead, the alloys of phosphorus and iron can be divided into five classes: (i) those containing 0–1·7 per cent. of phosphorus and consisting of solid soln. of Fe_3P in iron; (ii) alloys with 1·7–10·2 per cent. of phosphorus, which form solid soln. of Fe_3P in iron and give a eutectic alloy (10·2 per cent. P) consisting of a definite solid soln. and the phosphide Fe_3P; (iii) those with 10·2–15·58 per cent. P, also consisting of the eutectic and Fe_3P, the m.p. of the latter (15·58 per cent. P) being 1060°; (iv) alloys containing 15·58–21·6 per cent. P and consisting of Fe_3P and Fe_2P; (v) those with more than 21·6 per cent. P and containing Fe_2P and another phosphide richer in phosphorus. The results of B. Sakalatwalla are illustrated by Fig. 25. The m.p. of iron is lowered from 1510° to about 1400° by the addition of 1·7 per cent. of phosphorus; by increasing the proportion of phosphorus to 10·2 per cent. the f.p. curve shows two arrests. The second one refers to the eutectic line which commences at about 886°, and rises to about 1003° as shown in the diagram. This unusual behaviour is attributed to the existence of a definite phosphide with between 6·5 and 8 per cent. of phosphorus, so that the corresponding eutectic has a different composition to that with 10·2 per cent. of phosphorus. The f.p. with increasing proportions of phosphorus rises from the eutectic to a maximum at about 1104° corresponding with the tritaphosphide; the f.p. curve then falls to a second eutectic about 960° with about 16·2 per cent. of phosphorus. The f.p. curve then rises to about 1275° corresponding with the hemiphosphide. Only one sample was examined with over this amount of phosphorus, and the alloy with 24·5 per cent. of phosphorus had arrests at 1295° and 1218°. Alloys with up to 1·7 per cent. of phosphorus are solid soln. of phosphorus in iron. N. S. Konstantinoff interprets his results rather differently as illustrated by Fig. 26. Here, the f.p. curve for alloys with up to 21 per cent. of phosphorus has three branches: (i) *AB*, falling from 1514°, the m.p. of iron, to 1020°, corresponding with 10·2 per cent. Fe; (ii) *BC*, rising continuously from *B* to *C*, and corresponding with the separation of crystals of the phosphide Fe_3P. The separate solidification curves exhibit two halts, one showing a regular rise corresponding with the separation of crystals of the phosphide, and the other at a constant temperature corresponding with separation of the eutectic and gradually diminishing in magnitude as *C* is approached. Micrographic examination of these alloys shows the presence of rhomboidal plates of Fe_3P surrounded by the eutectic; (iii) *CD*, rising at first rapidly and afterwards more slowly to the point *D*, corresponding with the phosphide Fe_2P. The second eutectic line alluded to by B. Sakalatwalla is shown by the dotted line *E'F'*. J. L. Haughton also found that the first eutectic at 1050° with nearly 10·5 per cent. phosphorus, consists of the α-solid soln. of phosphorus in iron, and the tritaphosphide. After this, the liquidus curve rises to 1166°, at which temp. the tritaphosphide is formed by a peritectic reaction between the liquid and the hemiphosphide, the latter corresponding with a maximum on the liquidus at 1380°. Beyond this point, the liquidus falls to a second eutectic, the constituents of which are the hemiphosphide and an unknown compound. The tritaphosphide forms no solid soln., but magnetic analysis shows that it undergoes a transformation at about 420°, which is similar to the corresponding transformation in cementite. The compound hemiphosphide forms no solid soln. with an excess of iron, but there may be a very slight range of solid solubility on the phosphorus side. The effect of phosphorus on the critical points is very marked. The A_4 point is rapidly depressed and the A_3 point raised, the two joining to form a completely enclosed area representing the existence of γ-iron. There is thus no boundary between α- and δ-iron, both of which form the same space lattice. H. Junglbluth and H. Gummert studied the effect of annealing on the development of the iron phosphide eutectic.

The microscopic structure of these alloys was also examined by these investigators, J. O. Arnold, J. E. Stead, N. S. Konstantinoff, E. Piwowarsky, and B. Sakalatwalla. The last-named found the hardness on Mohs' scale rose from that of pure iron, 3·5, to between 5 and 5·5 with the smallest addition of phosphorus. The hardness remained constant till in the neighbourhood of the first eutectic, Fig. 25, it rose to 6 with a sample containing 9·93 per cent. of phosphorus, and remained constant up to the first maximum; on passing the second eutectic the hardness rose to 6·5 with a sample containing 16·1 per cent. of phosphorus. The hardness was thereafter lowered with an increasing proportion of phosphorus. The greater hardness of samples with eutectic proportions of the constituents is attributed to the closer grain of the fine eutectic structure as contrasted with the large, homogeneous, crystalline faces presented by the individual components of the non-eutectics. E. d'Amico also studied the hardness of these alloys. C. J. B. Karsten reported that the tenacity of iron is not sensibly affected by the presence of up to 0·3 per cent. of phosphorus, although the metal is a little harder. Iron with 0·6 per cent. of phosphorus will not stand the breaking test, but it can be bent at right angles without breaking; with 0·66 per cent. of phosphorus, the qualities of the iron are not those characteristic of cold-short iron properly so called. The tenacity is notably reduced with 0·75 per cent. of phosphorus, and with 0·8 per cent. the iron is decidedly cold-short; and with 1·0 per cent., a bar cannot be bent at right angles. All iron with over one per cent. of phosphorus is brittle. E. d'Amico found the elastic limit of steel with 0·125 per cent. of carbon was raised about 27 kgrms. per sq. mm. by the addition of each 0·1 per cent. of phosphorus; the tensile strength was raised by 0·5 per cent. of phosphorus, but fell off with higher proportions. The elongation and contraction followed the tensile strength, falling off as the phosphorus rose, and becoming nil with higher proportions. H. M. Howe, A. Ledebur, T. D. West, and J. E. Stead also studied the effect of phosphorus in the presence of varying amounts of carbon on the tensile strength of iron and steel. E. d'Amico found the electrical resistance of phosphorized iron and steel increased as the proportion of phosphorus increased; but the magnetic qualities were influenced by phosphorus only in so far as its presence makes mechanical and thermal treatment impossible. R. Kremann and O. Baukovac studied the electrolysis of iron phosphides.

Several of the phosphides which have been reported are of doubtful individuality. They have been formed in most cases by the direct union of phosphorus and iron. At a dull red-heat, the monophosphide is formed; at a bright red-heat, the hemiphosphide; and at a white-heat, iron retains only a moiety of phosphorus. J. Percy described square prismatic crystals of *iron hexitaphosphide*, Fe_6P, said to be formed by the action of phosphorus on iron at a red-heat. The product was in all probability a mixture of iron and the tritaphosphide. T. Sidot reported *iron tetritaphosphide*, Fe_4P, to be formed by passing the vapour of phosphorus over iron, and afterwards, with the intention of volatilizing the excess of phosphorus, calcined the product in an ordinary crucible. On breaking the fused and cooled mass, the interior was found to be studded with beautiful crystals, many of which were nearly a centimetre in length. The crystals were right prisms with a square base; generally iridescent upon the surface; they were strongly magnetic, and possessed a hardness comparable to that of steel. He suggested that the crystals are isomorphous with rhabdite—*vide infra*—and consequently T. Sidot's product was probably a mixture of iron and the tritaphosphide. H. H. Hvoslef, and H. le Chatelier and S. Wologdine, prepared **iron tritaphosphide,** Fe_3P, by melting the elements together. The iron phosphide can be separated from the cold pulverized product by means of a magnet or by melting copper phosphide with the necessary amount of iron when the tritaphosphide rises to the surface as a separate phase. E. Mallard observed tetragonal crystals of an iron phosphide, approximating FeP(As), were formed by combustion in the coal mines of Commentary, France. The conditions of stability are indicated in Figs. 25 and 26, where, according to B. Sakalatwalla, the m.p. is 1104°, and, according to N. S. Konstantinoff, the m.p. is 1155°; but J. L. Haughton found that the tritaphosphide is formed by a peritectic reaction at about 1166°. H. le Chatelier and S. Wologdine gave 1100° for the m.p., and 6·74 for the sp. gr. L. J. Spencer found that the axial ratio of the tetragonal crystals is $a:c=1:0·3469$. The magnetic transformation point is 445°–435° —*vide supra*. This phosphide dissolves in hydrochloric acid with the production of hydrogen: $2Fe_3P+12HCl+8H_2O=6FeCl_2+2H_3PO_4+11H_2$. O. Kuhn reported **iron dipentitaphosphide,** Fe_5P_2, to be formed by melting together a mixture of bone-ash with ferruginous quartz, charcoal, powder, and copper. When the product was digested in nitric acid, glistening, needle-like crystals of this phosphide remained. The crystals were insoluble in hot or cold, conc. nitric acid, and dil. sulphuric acid. They were readily soluble in aqua regia. The crystals cannot be regarded as a solid soln. of iron tritaphosphide and hemiphosphide since the former is readily soluble in nitric acid. M. Boblique also reported the dipentitaphosphide, but H. le Chatelier and S. Wologdine could find no evidence of its existence. A. Granger obtained **iron tritetritaphosphide,** Fe_4P_3, to be formed by passing a current of phosphorus trichloride over reduced iron; the vapour of phosphorus diiodide acts similarly, but at a lower temp. H. Struve reported it to be formed in an impure state, but C. Freese doubted its existence. A. Granger's product lost its phosphorus at a red-heat. The grey, prismatic crystals were but little affected by aqua regia, but were freely attacked by chlorine, and fused alkali hydroxides. The analyses of the phosphides prepared by J. J. Berzelius, F. Wöhler, C. Hatchett, H. Davy, H. Struve, P. Berthier, and B. Pelletier corresponded with **iron hemiphosphide,** Fe_2P. It was obtained by C. Freese by heating a mixture of iron phosphate and lamp-black in a covered crucible for 4 hrs. at a white-heat. It appeared as a pale grey crystalline powder of sp. gr. 5·74. G. Maronneau obtained it by heating copper phosphide with one-tenth of its weight of iron turnings in an electric furnace, and isolating the product by treatment with conc. nitric acid. The sp. gr. was 6·57. H. le Chatelier and S. Wologdine made it in a similar manner, and from its elements, and by reducing iron phosphate by the aluminothermite process. This phosphide appears in pale grey, needle-like crystals. The conditions of stability are indicated in Figs. 25 and 26. C. Freese gave 5·74 for the sp. gr.; G. Maronneau, 6·57; and H. le Chatelier and S. Wologdine, 6·56. B. Sakalatwalla gave 1275° for the m.p.; N. S. Konstantinoff, 1350°; J. L. Haughton, 1380°; and H. le Chatelier and S. Wologdine, 1290°. The last-named gave 80° for the magnetic transformation point, and found it to be 50 times less magnetic than the tritaphosphide. The steel-grey prismatic crystals were found by J. J. Berzelius, H. Struve, and C. Freese to pass into ferric phosphate when heated in air; they were insoluble in all acids, and in a mixture of nitric and hydrofluoric acids. G. Tammann and H. Bredemeier studied the surface oxidation of the hemiphosphide, as well as the films produced by the halogens. H. Moissan said that this phosphide is attacked by fluorine at a red-heat. R. Schenck added ferrous sulphate to a flask from which phosphuretted hydrogen was being evolved by the action of potash-lye on phosphorus. The black pulverulent, and magnetic **iron ditritaphosphide,** Fe_3P_2, so obtained was washed by decantation, then with water, with alcohol, and with ether. It readily oxidized on exposure to air; and ignited below 100°, forming a reddish-brown powder. It dissolved slowly in dil. or conc. boiling acids, forming hydrogen and phosphine. C. Freese, A. Schrötter, and H. H. Hvoslef prepared **iron monophosphide,** FeP, by heating ferrous sulphide in a current of phosphine: $2FeS+2PH_3=2FeP+2H_2S+H_2$, or by passing a mixture of hydrogen and phosphorus vapour over red-hot iron; while H. le Chatelier and S. Wologdine made it by passing the vapour of phosphorus over red-hot, powdered iron hemiphosphide. L. M. Dennis and B. S. Cushman made it by heating ferric chloride at a red-heat with phosphine: $FeCl_3+PH_3=FeP+3HCl$. The black crystalline mass was found by A. Schrötter to have a sp. gr. of 5·21; and H. le Chatelier and S. Wologdine gave 5·76, and 48° for the magnetic transformation point. It was found to be 1·5 times more magnetic than the hemiphosphide. H. Rose reported **iron tetratritaphosphide,** Fe_3P_4, to be formed by the action of phosphine on gently warmed iron pyrites: $3FeS_2+4PH_3=Fe_3P_4+6H_2S$. C. Freese also obtained it by passing phosphine over heated iron, or ferrous chloride; and A. Granger by the action of phosphorus trichloride on red-hot iron. The dark grey powder has a sp. gr. 5·04. It passes into one of the lower phosphides when heated in hydrogen. According to H. Rose, the product gave the phosphorus flame when heated in the blowpipe flame; it dissolved in nitric acid and aqua-regia, but not in conc. or dil. hydrochloric acid. H. le Chatelier and S. Wologdine prepared **iron hemitriphosphide,** Fe_2P_3, by passing the vapour of phosphorus dichloride in a stream of hydrogen over reduced iron. A. Granger obtained this phosphide—*iron sesquiphosphide*—by carrying phosphorus vapour over heated ferric chloride by means of a current of carbon dioxide. H. le Chatelier and S. Wologdine found that the steel-grey crystals have a sp. gr. of 4·5. The magnetic permeability is one-seventy-fifth part of that of the monophosphide, and 30 times that of water. The permeability increases slowly as the temp. falls to —50°, but no magnetic transformation point could be found. According to A. Granger, the sesquiphosphide is insoluble in hydrochloric and nitric acids and in aqua regia; does not alter when heated in air to dull redness, but loses phosphorus at a bright red-heat; and is slowly attacked by chlorine at dull redness, and by bromine at a higher temp.

J. E. Stead showed that on melting sat. solid soln. of iron phosphide in iron and carbon alloys, the carbon causes a separation of phosphide near to the point of solidification, which appears as a eutectic in irregular-shaped areas; a residuum appears to be retained by the pearlite. E. D. Campbell and S. C. Babcock investigated the solubility of phosphorus in carbon steels. The ternary system: Fe–C–P, was studied by J. E. Stead, F. Wüst, and P. Goerens and co-workers. According to F. Wüst, the temp. at which sat. iron-carbon alloys begin to solidify is lowered by the addition of phosphorus, 1 per cent. of phosphorus causing a depression of 27°. When the proportion of phosphorus exceeds 6·7 per cent., the f.p. again rises. The ternary eutectic melts at 950°, and contains 6·7 per cent. P, 2·0 per cent. C, and 91·3 per cent. Fe. The eutectic disappears at a phosphorus content of 15 per cent., corresponding with the phosphide Fe_3P. Alloys containing between 6·7 per cent. and 15 per cent. of phosphorus show crystals of the phosphide.

The solubility of carbon in iron is reduced by the addition of phosphorus, but the temperature of formation of the eutectoid pearlite is not influenced by the presence of the phosphide. P. Goerens and W. Dobbelstein gave for the composition of the ternary eutectic *E*, Fig. 27, at 953°, 1·96 per cent. of carbon, 6·89 per cent. of phosphorus, and 91·15 per cent. of iron; and J. E. Stead, respectively 1·92, 6·89, and 91·19. In Fig. 26, *A* represents the iron-phosphorus eutectic, and *B*, the iron-carbon eutectic. They showed that when sat. solid soln. of iron phosphide in iron are heated or cooled they show no critical point at Ar_3, and the structure is not broken up even when the temp. exceeds 1000°. There can therefore be no allotropic change from β- to γ-iron by heating to 1000°. "When, however, carbon passes into the mass, a large proportion of the phosphide is expelled, and the carbon absorbed converts, at the temperature of the cementation furnace, a dominating proportion of the β-iron into γ-iron, and coincidentally the structure is entirely reorganized and recrystallization is effected. The recrystallization can only proceed coincidentally with the penetration of the carbon from the exterior towards the centre. Under favourable conditions the slowly developing crystalline grains develop longitudinally into columns, which radiate to the middle of the bar. A similar condition of crystalline development follows the change of allotropic state, but in the reverse direction, when carburetted steel is decarburized in ore or limestone at about 750°. At that temp. in presence of diffused carbide the carbon is in the γ-state, but as the carbon is removed β-iron is formed and crystallization of the iron proceeds from the exterior to the centre of the mass, leaving a most perfect columnar structure." J. O. Arnold and A. McWilliam showed that iron phosphide will diffuse from iron with 1·36 per cent. of phosphorus into pure iron when placed in close contact, and heated in vacuo for 10 hrs. at 1000°. The relative speeds of diffusion of carbon and phosphorus are as 5 : 1. J. E. Stead also noted this phenomenon. F. Osmond, H. M. Howe, and J. E. Stead observed that the Ac$_3$-critical temp. of iron is raised by phosphorus—0·417 changing the Ac$_3$ temp. from 820° to 870° if the initial ingot structure was removed by annealing, and to 950° if it was not removed. As F. Osmond puts it, phosphorus preserves the α-iron at a high temp. A. Carnot and E. Goutal found that hardening steel in the presence of manganese exerted no influence on the way iron and phosphorus combine. M. Lencauchez observed that when carbon dioxide acts on heated phosphorized pig-iron, carbon monoxide is formed by the abstraction of carbon from the iron, and much of the phosphorus is at the same time eliminated. According to J. E. Stead, the proportion of phosphine given off on dissolving phosphoretic irons free from carbon is approximately inversely in proportion to the amount of phosphorus. When 1·7 per cent. is present, only about 4 per cent. of it escapes as gas, whereas when there is only from 0·03 to 0·10 per cent., nearly 70 per cent. of it passes off as phosphine. When carbon is introduced into irons containing from 0·03 to 0·10 per cent. phosphorus, the proportion of phosphine liberated on solution of the metal steadily decreases with each increment of carbon, until, when the latter reaches about 1·2 per cent., only 15 per cent. of the whole escapes as phosphine. This behaviour leads to the conclusion that there are two soln. in steel above its solidifying point, a soln. of carbide and a soln. of phosphide; that the carbon soln. is the dominant one; and that the soln. of phosphide is conc. more and more into that portion of the iron not dominated by the carbon. The more the soln. of phosphide becomes conc. by the carbon, the less proportion of it is capable of yielding phosphine when it is treated with acid.

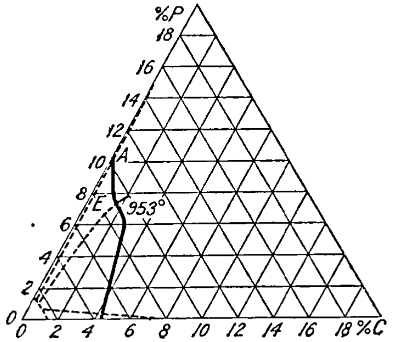

FIG. 27.—The Fusion Curves of a Portion of the Ternary System: Fe–C–P.

According to B. Pelletier,[28] an alloy of cobalt and phosphorus is formed when pieces of phosphorus are projected on red-hot cobalt; and by igniting a mixture of cobalt with glacial phosphoric acid and charcoal powder; while P. Berthier made the alloy by heating white-hot a mixture of cobalt or cobalt oxide, bone-ash, powdered quartz, and charcoal, and H. Rose, by the action of phosphine on heated cobalt chloride, or by igniting the phosphate in a stream of hydrogen. P. Kulisch found that phosphine precipitates a mixture of cobalt and its phosphide from ammoniacal soln., but it gives no precipitate with acid or neutral soln. I. Schepeleff and F. S. Schemtschuschny determined the f.p. curve for a number of alloys of cobalt and phosphorus, and the results are illustrated by Fig. 28. The tritaphosphide of cobalt corresponding with that of iron and of nickel does not appear on the diagram; but **cobalt hemiphosphide,** Co_2P, is formed. A. Granger made it by heating reduced cobalt at as high a temp. as possible in a porcelain tube through which the vapour of phosphorus trichloride is passed; and G. Maronneau obtained it by heating a mixture of copper phosphide and cobalt filings in an electric arc furnace for five minutes. The steel-grey mass consisting of needle-like crystals has a sp. gr. 6·4 at 15°. I. Schepeleff and F. S. Schemtschuschny gave 1386° for the m.p.; 4 for the hardness; and 6·3 to 6·6 for the sp. gr. It is less magnetic than the metal. According to A. Granger, and G. Maronneau, the phosphide is slowly decomposed by hydrochloric acid; is freely dissolved by nitric acid and by aqua regia; and it is decomposed by chlorine, and fused alkali hydroxides. H. Rose made **cobalt ditritaphosphide,** Co_3P_2, by passing phosphine over red-hot cobalt chloride; and by heating the phosphate in a current of hydrogen; while A. Schrötter made it by passing the vapour of phosphorus over reduced cobalt. The pale grey crystalline mass had a sp. gr. 5·62. H. Rose said that the black powder does not give the phosphorus flame when heated before the blowpipe; but when heated in chlorine it burns, forming phosphorus and cobalt chlorides. It is insoluble in conc. hydrochloric acid, but readily dissolved by nitric acid. By warming cobalt chloride at a dull red-heat, in phosphorus vapour, and boiling the products of the reaction with dil. hydrochloric acid, A. Granger obtained a black, non-magnetic brittle mass of **cobalt hemitriphosphide,** Co_2P_3. It decomposes at a bright red-heat; it is insoluble in hydrochloric and nitric acids, and in aqua regia; and is likewise attacked by chlorine at a high temp.

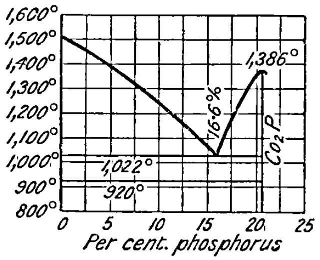

FIG. 28.—The Freezing-point Curves of Cobalt-Phosphorus Alloys.

According to B. Pelletier, a nickel phosphide is formed energetically when pieces of phosphorus are projected on red-hot nickel or by fusing a mixture of glacial phosphoric acid, nickel, and charcoal. W. A. Lampadius used similar processes. P. Berthier obtained a phosphide by fusing a mixture of nickel or nickel oxide, bone-ash, powdered quartz, and charcoal in a graphite crucible; H. Davy, by passing the vapour of phosphorus over red-hot nickel; C. F. Rammelsberg, by calcining the hypophosphite; and A. Oppenheim, by boiling a soln. of nickel oxide in aq. ammonia with phosphorus. P. Kulisch found that neutral and acid soln. of nickel salts are not changed by phosphine, but ammoniacal soln. give a black precipitate which is a variable mixture of nickel and its phosphide. N. S. Konstantinoff plotted the f.p. curve of alloys of nickel and phosphorus, and the results are shown in Fig. 29. Three nickel phosphides are indicated on the diagram. The first, **nickel tritaphosphide,** Ni_3P, freezes at about 965°, and it appears in rhombic plates; the second compound is **nickel dipentitaphosphide,** Ni_5P_2. Its formation was reported by B. Pelletier, W. A. Lampadius, and P. Berthier by the methods indicated above. A. Granger obtained it by the action of phosphorus trichloride on nickel at a red-heat; the product with phosphorus triiodide was not of constant composition. The dipentitaphosphide appears in needle-like or tabular crystals, which J. Garnier consider to be tetragonal. B. Pelletier said that the compound is non-magnetic and more fusible than nickel. The m.p. given by N. S. Konstantinoff is 1185°, and he found that there are two modifications with a transition point at 1035°. The β-dipentitaphosphide dissolves in the hemiphosphide, and the solid soln. separates into the hemiphosphide and α-dipentitaphosphide at about 1000°. A. Granger said that this phosphide loses phosphorus at a high temp., and is attacked by chlorine, and by molten alkali hydroxides. The third phosphide appearing on the f.p. diagram, Fig. 29, is **nickel hemiphosphide,** Ni_2P. H. Struve made it by heating nickel pyrophosphate alone at a white-heat, or in a stream of hydrogen; R. Schenck, by the method he employed for the iron phosphide (*q.v.*); A. Granger and co-workers, by heating reduced nickel in a current of phosphorus trichloride at about 600°; and G. Maronneau, by heating a mixture of copper phosphide and nickel filings for 5 minutes in the electric arc furnace. The products obtained by R. Schenck's process is black; the others give a greyish-white mass. The conditions of equilibrium are indicated in Fig. 29; and N. S. Konstantinoff added that it has a great tendency to crystallization, forming long, steel-grey needles. G. Maronneau gave 6·3 for the sp. gr. at 15°; and N. S. Konstantinoff, 1112° for the m.p. The hemiphosphide was found by A. Granger to lose some phosphorus when heated to a high temp. It is decomposed by chlorine, and fused alkali hydroxide; it is insoluble in acids; but freely soluble in a mixture of nitric and hydrofluoric acids. The product obtained by H. Davy, and A. Schrötter by the action of phosphorus vapour on nickel corresponded with **nickel ditritaphosphide,** Ni_3P_2; H. Rose obtained it by the action of phosphine on red-hot nickel sulphide or chloride, and he said that it is produced by calcining nickel pyrophosphate—but H. Struve obtained the hemiphosphide by this process. A. Schrötter gave 5·99 for the sp. gr. of the greyish-white mass. It is not affected by hydrochloric acid, but is easily dissolved by nitric acid. A. Granger reported **nickel hemitriphosphide,** Ni_2P_3, to be formed by passing phosphorus vapour in a stream of carbon dioxide over red-hot nickel chloride. The grey crystalline mass looks like graphite. It is not altered when heated to redness, but in the gas flame it loses phosphorus, and fuses to a metallic-looking mass. The hemitriphosphide is not magnetic; it is not affected by hydrochloric or nitric acid, or by aqua regia; chlorine attacks it when heated.

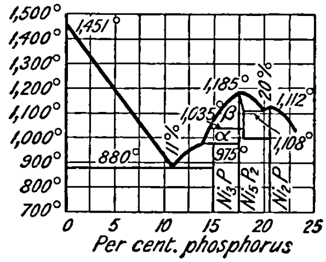

FIG. 29.—The Freezing-point Curves of Nickel-Phosphorus Alloys.

The association of phosphorus with iron and nickel in meteorites was recognized by J. J. Berzelius,[29] about 1832; and, on account of the slow solubility of the iron nickel phosphide in acids, C. U. Shepard called it a complex phosphide, *dyslytite*—from δύσλυτος, difficult to dissolve—and shortly afterwards, W. Haidinger called it **schreibersite**—after C. F. A. von Schreiber. The term schreibersite had previously been applied by C. U. Shepard to a chromium sulphide. Analyses of the **iron nickel phosphide** from various meteorites were made by N. W. Fischer, C. F. Rammelsberg, J. J. Berzelius, J. L. Smith, C. Bergemann, and H. Müller; and J. L. Smith summarized the results of his analyses by $Fe_2(Ni,Co)P$; S. Meunier gave a similar formula; and E. Cohen, $(Fe,Co,Ni)_3P$. C. von Reichenbach, and W. Haidinger disagreed on the use of the term schreibersite, and the former proposed the name *bamprite* or *iron glance* for a constituent of meteorites which had a metallic lustre and tin-white colour. This was shown to be mainly cohenite. F. Wöhler applied the term *partschite*—after P. M. Partsch—to a form of iron nickel phosphide occurring in meteorites in four-sided prismatic crystals; and G. Rose employed the term **rhabdite**—from ῥάβδος, a rod—for the complex phosphide occurring in minute tetragonal prisms or needles distributed parallel to the cubic edges of various meteoric irons. The term schreibersite then came to be applied to that constituent of these meteorites which occurred in steel-grey folia and grains; and rhabdite, to that occurring in needle-like crystals. Analyses were also made by C. Winkler, E. Cohen, A. Brezina and E. Cohen, E. Cohen and E. Weinschenk, E. D. Kislakowsky, N. S. Maskelyne, W. Flight, J. Domeyko, S. Meunier, C. A. Joy, H. Wichelhaus, A. Daubrée, B. Silliman and T. S. Hunt, E. Mallard, O. A. Derby,

E. Hussak, G. Florence, J. A. Antipoff, G. P. Merrill, W. Tassin, etc. H. E. Törnebohm reported schreibersite in the terrestrial iron of Ovifak, although E. Cohen could not find it there; G. vom Rath reported rhabdite in some pig-iron. A. Faye, E. Jannettaz, J. Garnier, and A. Daubrée discussed the synthesis of these phosphides. E. Mallard identified the iron phosphide he obtained as the result of a coal-mine fire —*vide supra*—with rhabdite. G. Tschermak, J. L. Smith, E. Cohen, and E. Cohen and E. Weinschenk showed that dyslytite, schreibersite, and rhabdite are probably the same thing; indeed, G. Tschermak found transition forms between acicular and foliated crystals—*i.e.* between schreibersite and rhabdite—in the meteorite of Braunau.

No definite *rhodium phosphide* has been reported. C. Claus[30] found that when the basic phosphate is heated in a current of hydrogen, the metallic-looking residue is a mixture of phosphorus and the metal. According to J. J. Berzelius, palladium unites with phosphorus at a high temp., forming a fusible *palladium phosphide.* R. Böttger found that when phosphine is passed into palladous salts, the precipitate is a mixture of phosphorus and metal. F. W. Clarke and O. T. Joslin obtained **iridium hemiphosphide,** Ir_2P, by projecting phosphorus on iridium at a white-heat. The product is as hard and resistant as iridium, and it loses its phosphorus when heated white-hot for some time. In this way, J. Holland was able to prepare objects of iridium shaped with the fusible alloy and afterwards converted into the iridium alone.

Platinum readily alloys with phosphorus. B. Pelletier[31] obtained an impure phosphide fusing platinum with glacial phosphoric acid and charcoal powder, and also by projecting phosphorus on red-hot platinum; E. Davy, by melting spongy platinum with phosphorus in an evacuated glass tube; and by heating ammonium chloroplatinate and phosphorus to dull redness; E. Davy, by the electrolysis of phosphoric acid with a platinum cathode; and W. C. Heraeus, by igniting magnesium pyrophosphate in a platinum crucible. According to A. Granger, phosphorus vapour acting on finely-divided platinum at 500° furnishes platinum diphosphide; at 600°, the pentatritaphosphide, and at a higher temp., the hemiphosphide. J. J. Berzelius also found that phosphorus vapour reacts with other platinum metals, forming, say, *palladium phosphide*, *iridium phosphide*, and *osmium phosphide.*

F. W. Clarke and O. T. Joslin prepared **platinum hemiphosphide,** Pt_2P, by heating the pentatritaphosphide; and A. Granger, by the action of phosphorus vapour on finely-divided platinum at 700°. The grey powder is sparingly soluble in aqua regia, and it is readily attacked by molten sodium carbonate. F. W. Clarke and O. T. Joslin prepared **platinum monophosphide,** PtP, along with the diphosphide by heating the pentatritaphosphide with aqua regia. A. Granger made **platinum pentitatriphosphide,** Pt_5P_3, by heating platinum sponge in phosphorus vapour at 600°; and F. W. Clarke and O. T. Joslin, by heating a mixture of platinum and phosphorus at a white-heat in a fireclay crucible. The silvery-white mass loses phosphorus when heated; and with aqua regia it furnishes the mono- and diphosphides. A. Schrötter, and A. Granger reported **platinum diphosphide,** PtP_2, to be formed by the action of phosphorus vapour on platinum at about 500°; and F. W. Clarke and O. T. Joslin, by heating the pentatritaphosphide with aqua regia. A. Schrötter gave 8·77 for the sp. gr. of the grey mass, and he found that when heated, it decomposes into the pentatritaphosphide and phosphorus. I. I. Saslawsky studied the mol. vol. It is insoluble in hydrochloric acid, and other acids, but soluble in aqua regia. It is decomposed by molten alkali hydroxides. P. Kulisch studied the action of phosphine on soln. of platinum chloride. The citron-yellow precipitate darkens, finally becoming nearly black. The proportion of platinum and phosphorus approaches that of the diphosphide—possibly **platinum dihydrodiphosphide,** PtH_2P_2. A. Cavazzi represented the reaction with phosphine: $PtCl_4+2PH_3=PtCl_2+2HCl+P_2H_4$; and $P_2H_4+PtCl_2=2HCl+PtH_2P_2$. The ochre-yellow product inflames in air between 100° and 110°; and also in contact with fuming nitric acid. It is insoluble in water and in hydrochloric acid.

§ 13. The Lower Oxides of Phosphorus

The main oxides of phosphorus with their acids are:

	Acids.
(Phosphorus tetritoxide, P_4O)	——
(Phosphorus hemioxide, P_2O)	Hypophosphorus acid, H_3PO_2
Phosphorous oxide, P_4O_6	Phosphorous acid, H_3PO_3
— —	Pyrophosphorous acid, $H_4P_2O_5$
— —	Metaphosphorous acid, $(HPO_2)_n$
Phosphorus tetroxide, P_2O_4	Mixed acids, H_3PO_3 and H_3PO_4
— —	Hypophosphoric acid, $H_4P_2O_6$
Phosphoric oxide, P_2O_5	Phosphoric acid, H_3PO_4
— —	Pyrophosphoric acid, $H_4P_2O_7$
— —	Metaphosphoric acid, $(HPO_3)_n$
— —	Monoperphosphoric acid, H_3PO_5
— —	Diperphosphoric acid, $H_4P_2O_8$

There are derivatives of phosphorous and phosphoric acids like pyrophosphoric and metaphosphoric acids, etc.; and also some more or less doubtful oxides like phosphorus tetritoxide. The early investigators speak of the formation of a suboxide under various conditions, but the subsequent discovery of red phosphorus by A. Schrötter[1] proved that in many cases the alleged oxide was an allotropic form of phosphorus. This is considered to have been the case with the red substance formed by the incomplete combustion of phosphorus by oxygen under water—H. A. von Vogel, J. Pelouze, and R. Böttger; by the incomplete combustion of a thin layer of phosphorus spread over a porcelain capsule to keep down the temp. and washing the product with water to remove phosphoric acid, and with phosphorus trichloride to remove yellow phosphorus—U. J. J. Leverrier; by the incomplete oxidation of phosphorus by heating it with ammonium nitrate—R. F. Marchand; and by boiling the phosphorus with an aq. soln. of iodic or periodic acid—M. Bengieser.

U. J. J. Leverrier exposed to air a soln. of phosphorus in ether or in phosphorus trichloride, washed the product in warm water, and dried it in vacuo over sulphuric acid. The analysis corresponded with **phosphorus tetritoxide**, P_4O. B. Reinitzer and H. Goldschmidt obtained a similar product by the action of phosphorus oxychloride on zinc, magnesium, or aluminium at 100°, or on yellow phosphorus at 250°. They added that the substance obtained with yellow phosphorus has the composition of phosphorus tetritoxide, but not its properties. Its properties approximate closely to those of red phosphorus.

According to H. Biltz, ammonia acts energetically on phosphorus pentoxide at ordinary temp., forming a dark reddish-brown mass of phosphamic acid, which, when treated with water, forms phosphine, yellow phosphorus, and a reddish flocculent mass of phosphorus tetritoxide—not red phosphorus as H. Schiff supposed. A 0·06 per cent. yield of the same oxide was formed by heating phosphorus pentoxide at 250° either in vacuo or in a current of air, carbon dioxide, hydrogen, oxygen, or steam. Traces were also produced by dissolving the pentoxide in water or soda-lye.

The formation of the tetritoxide is said to be conditioned by the high temp., and by the presence of trioxide in the pentoxide. It is not formed by the action of a large excess of water, or ammonia; nor when the pentoxide has been purified by sublimation over platinum black in the presence of oxygen. Some tetritoxide was formed by heating the pentoxide for several hours at 230°, so that this treatment was not sufficient to remove all the trioxide which boils at 173°, or else the commercial pentoxide contains small quantities of other lower oxides of phosphorus. A. Stock observed the formation of the tetritoxide when yellow phosphorus is heated above its m.p. in liquid ammonia; the resulting black powder is considered to be a mixture of phosphamide and tetritoxide. The amide decomposes in presence of water, moist air, or acids; $2P_2NH_2+H_2O=P_4O+2NH_3$. Phosphorus tetritoxide is obtained by withdrawing water from hypophosphorous acid; thus, A. Michaelis and M. Pitsch made it by treating hypophosphorous acid with water: $4H_3PO_2=2P_2O+6H_2O$; $2P_2O=P_4O+O$; hydrochloric acid, acetyl chloride, or phosphorus trichloride can be used in place of water: $4H_3PO_2+2PCl_3=H_3PO_3+H_3PO_4+6HCl+P_4O$; but A. Geuther found that the actions of phosphorus trichloride on the acids of phosphorus furnish red phosphorus. C. H. Bothamley and G. R. Thompson said some tetritoxide is produced by the action of phosphorus trichloride on phosphoric acid—*vide infra,* the preparation of phosphorous oxide. Commercial hypophosphorous acid nearly always contains lime so that the product is affected accordingly.

A. Michaelis and K. von Arend prepared the tetritoxide by evaporating hypophosphorous acid on a water-bath, mixing it with absolute alcohol and dry ether to remove the calcium salts. The alcohol and ether are distilled from the filtrate, and the residue evaporated on the water-bath. Thirty grms. of hypophosphorous acid so purified are dissolved in 100 grms. of glacial acetic acid, and treated with 90 grms. of acetic anhydride. The mixture was thoroughly mixed by shaking and poured into 1 to 2 litres of ice-cold water. The tetritoxide was allowed to settle; and, after decantation of the mother-liquor, washed with ice-cold water, and alcohol. The product was dried over phosphorus pentoxide in vacuo.

A. Michaelis and K. von Arend used ammonium hypophosphite in place of the acid: $5(NH_4)H_2PO_2=P_4O+H_3PO_3+6H_2O+5NH_3$. T. E. Thorpe and A. E. H. Tutton said that the tetritoxide is produced when phosphorus trioxide is decomposed by hot water. According to A. Michaelis and M. Pitsch, phosphorus dissolves in a mixture of one vol. of a 10 per cent. soln. of sodium hydroxide, and 2 vols. of alcohol, producing a dark red liquid with the elimination of hydrogen. When the filtered soln. is slowly acidified with dil. hydrochloric acid, a greenish-yellow precipitate of phosphorus tetritoxide is formed. The precipitate can be washed by decantation several times with hot water; collected on a filter, and washed successively with hot water, boiling alcohol, and ether. The product was dried on a porous plate in vacuo; and, after being ground to powder, again dried over phosphorus pentoxide for several days. This mode of preparation was also employed by A. Michaelis and K. von Arend, and D. L. Chapman and co-workers. A. Michaelis and M. Pitsch also obtained the tetritoxide by using solid hydrogen phosphide in place of phosphorus: $P_4H_2+H_2O=P_4O+2H_2$. A. Terni and C. Padovani obtained it by heating stannic chlorohypophosphite to 190°, and cooling the mass as soon as redding begins. On extraction with conc. hydrochloric acid, the tetritoxide remains undissolved.

The products obtained by these different processes vary in colour from dark brown through orange to scarlet-red, or even pale yellow, according to the state of subdivision. A. Michaelis and M. Pitsch gave 1·9116–1·9123 for the sp. gr. at 26°; and B. Reinitzer and H. Goldschmidt gave 1·48. The properties of the tetritoxides prepared by the action of zinc and of phosphorus on phosphoryl chloride are so different that B. Reinitzer and H. Goldschmidt suggested that two different forms of the tetritoxide exist. One form reduces salts of silver, gold, and mercury; the other does not. From the description of the properties of the product derived from the use of phosphorus, impure red phosphorus not the tetritoxide was in question.

A. Michaelis and M. Pitsch thus describe the properties of the tetritoxide When thoroughly dried, it is almost odourless, but a trace of moisture imparts to it the odour of phosphine; in the former condition, also, it may be heated in air to a comparatively high temp. without becoming ignited, but when moist it burns readily after being heated at 90° during several hours. If dried and heated in an indifferent gas, phosphorus distils over, leaving phosphoric oxide. Chlorine converts the dried oxide into phosphorus oxychloride and phosphorus pentachloride, the damp substance being oxidized to phosphoric acid, which is also produced by the action of sodium hypochlorite and of warmed sulphuric acid, the latter becoming reduced to hydrogen sulphide. Conc. nitric acid ignites the substance, which is indifferent towards hydrochloric acid. Many metals are precipitated by it from soln. of their salts either in metallic form, or as phosphorus compounds. A soln. of sodium or potassium hydroxide in aq. alcohol dissolves phosphorus tetritoxide, forming a deep red soln. which transmits only light between the C and D lines of the spectrum; when warmed, or on standing at the ordinary temp., this soln. evolves hydrogen and phosphine, sodium hypophosphite remaining dissolved. The oxide is coloured brown by ammonia, but the latter is removed on exposure to air, and the substance regains its orange-red hue. The presence of both alkali-lye and alcohol appear to be necessary for the dissolution of the tetritoxide; possibly an alcoholate is formed $NaO—P_4—OC_2H_5$, which is decomposed by acids or carbon dioxide and the tetritoxide precipitated: $NaO.P_4.OC_2H_5=P_4O+C_2H_5ONa$.

The analyses of the tetritoxide by U. J. J. Leverrier, B. Reinitzer and H. Goldschmidt, and A. Michaelis and M. Pitsch are in agreement with the empirical formula P_4O, which can be represented graphically:

$$\begin{matrix}P-P\\ \ddot{P}-\dot{P}\end{matrix}\!>O$$

G. le Bas also found this formula to be in harmony with the mol. vols. of the contained elements. A. Schrötter's view that the red product is impure red phosphorus was accepted by D. L. Chapman and co-workers because the analyses range from 86·50 to 94·52 per cent. of phosphorus, showing that the composition is variable, and hydrogen is present in considerable quantity. It is hence concluded that the alleged suboxide is red phosphorus whose microscopic particles have adsorbed water and undergone surface oxidation. A. Stock said that the samples of the tetritoxide which have been prepared retain hydrogen and water so tenaciously that the analyses *sehr annahernd den für* P_4O *berechneten Gehalt besitzt*. R. Schenck said that the tetritoxide behaves towards alcoholic alkali-lye like red phosphorus towards piperidine, and suggested that it is possibly a solid hydrogen phosphide mixed with finely-divided red phosphorus. A. Besson also regarded the tetritoxide as a mixture of red phosphorus, solid hydrogen phosphide, and phosphorus hemioxide. K. C. Browning considered that the tetritoxide can exist under certain unspecified conditions. A. Stock and co-workers, and A. Gutbier had doubts about the veritable existence of the tetritoxide as a chemical individual.

In the preparation of phosphorus tetritoxide by exposing to air for 24 hrs. yellow phosphorus under a layer of phosphorus trichloride, a thick white crust is formed on the surface of the phosphorus; and above and below this a yellow layer of a complex with the composition $4P_4O.3P_2O_5$. The phosphorus trichloride is decanted off, the pieces of phosphorus to which the complex adheres are separated from one another and put into water. The complex dissolves in water, forming a yellow soln. which is poured off from the phosphorus. At 80°, the product decomposes into phosphoric acid, and yellow flakes of a hydrated phosphorus suboxide of unknown composition.

According to A. Gautier,[2] when phosphorus trichloride is heated with crystalline phosphorous acid to 170° in a sealed tube, it furnishes a reddish-brown mass, the colour of which is due to the deposition of red phosphorus, according to the following equation: $3PCl_3+7H_3PO_3=4P+3H_4P_2O_7+9HCl$. If, however, the temp. is not allowed to rise beyond 79°–80°, hydrochloric and pyrophosphoric acids are still formed, but a bright yellow substance gradually separates, which may be purified by distilling off the excess of phosphorous chloride, and washing the residue with ice-cold water. The yellow powder thus obtained, dried first *in vacuo*, then at 140° in a current of carbon dioxide, has the composition of **phosphorus tetritahydroxide**, P_4HO. If the reaction is allowed to take place at a temp. above 80°, the product is contaminated with amorphous phosphorus. R. Boulouch obtained the same substance by dissolving phosphorus tetritiodide in potassium hydroxide: $P_4I+KOH=KI+P_4OH$; or by dissolving the tetritiodide in a soln. of potassium hydroxide, or carbonate, and adding hydrochloric acid to the liquor. The compound P_4HO is yellow, amorphous, unchangeable in dry air, but undergoes oxidation in moist air. It is insoluble in all the solvents employed, water, alcohol, ether, benzene, chloroform, essence of turpentine, even at 150°, glycerol, acetic acid, phosphorous acid, and phosphorous or antimonious chloride. It is a very stable body, and may be heated to 250° in dry carbonic anhydride, without losing weight. Towards 265° it evolves phosphine, and sets free a little common phosphorus, but it is only at 350°–360° that the phosphorus volatilizes freely, leaving an oxidized residue which attacks the glass. The compound is not affected by dil. acids, but ordinary nitric acid attacks it so violently as to produce a bright light. Water at 170° decomposes it easily, with evolution of pure phosphine—$2P_4HO+11H_2O=5PH_3O_2+PH_3O_3+2PH_3$. Very dil. alkaline soln. act upon the body P_4HO, causing the disengagement of a mixture of phosphine and hydrogen, and furnishing soln. of phosphate and hypophosphite, together with an insoluble brown substance, which when exposed wet to the air, seems to reproduce the original compound. Ammonia unites directly with P_4HO, producing a compound from which ammonia is withdrawn by the action of heat or of hydrochloric acid. A. Michaelis and M. Pitsch regard this hydroxide as a mixture of phosphorus tetritoxide and phosphorous acid. A. Gautier also found that the yellow powder often produced in the decomposition of phosphorus diiodide by water is similar in some respects to the preceding. It appears to be invariably formed when the iodide is decomposed by a large quantity of water. Analyses lead to the formula P_5H_3O, and the formation of the body may be explained by the following equation: $12PI_2+24H_2O=P_5H_3O+3PH_3O_4+3PH_3O_3+PH_3O_2+24HI$. During the reaction there is disengaged a quantity of phosphine, resulting from the further action of water upon the yellow body: $P_5H_3O+6H_2O=PH_3O_3+2PH_3O_2+2PH_3$. The compound P_5H_3O forms an unstable compound with ammonia. A. Michaelis and M. Pitsch consider this compound to be a mixture of phosphorus tetritoxide with solid hydrogen phosphide. K. I. Lissenko supposed the yellow precipitate to be hydrogen diphosphide. A. Gautier also found that when P_5H_3O is heated gradually to 275° in a current of carbon dioxide, it evolves phosphine, and leaves a residue which undergoes no further decomposition till the temp. is raised to 350°, and to which analysis assigns the formula, $P_{13}H_3O_3$: $3P_5H_3O=2PH_3+P_{13}H_3O_3$. Here again a mixture is probably involved and not a true compound.

A. Besson[3] reported that he had made **phosphorus hemioxide**, P_2O, (i) by warming a mixture of phosphoryl chloride and phosphonium bromide in a sealed tube at 50°: $POCl_3+PH_4Br=3HCl+HBr+P_2O$; (ii) by heating a conc. soln. of phosphorous acid and an excess of phosphorus trichloride in a reflux condensor: $PCl_3+H_3PO_3=3HCl+P_2O_3$; and $2P_2O_3=P_2O+P_2O_5$; and (iii) by the action of a current of air on a soln. of phosphorus in carbon tetrachloride. A. Besson said that the products obtained by the different processes are the same. The yellowish-red hemioxide is stable at 100°, but it gives off oxygen when heated to 135° in vacuo. It is not affected by water at ordinary temp., but when a mixture of the two is heated in a sealed tube at 100°, phosphorous acid is formed: $P_2O+O_2+3H_2O=2H_3PO_3$. It becomes incandescent in chlorine at ordinary temp.; chlorine dissolved in carbon tetrachloride forms phosphorus tri- or penta-chloride; bromine, phosphoryl bromide; and iodine, phosphorus diiodide. The hemioxide is probably contaminated with a little phosphorus and solid hydrogen phosphide; and A. Michaelis and M. Pitsch hold that it is the tetritoxide contaminated with some acids of phosphorus as well. K. Weidner supported A. Michaelis and M. Pitsch's assumption that A. Stock and M. Rudolph said that this compound may possibly be formed by the action of acids on a soln. of P_4S_3 in alkali-lye. If these contain the hemioxide, there is no relation between it and H_3PO_2; though the anhydride of this acid, P_2O, is the hemioxide, just as the anhydride of phosphorous acid is P_2O_3, and of phosphoric acid, P_2O_5. L. J. Chalk and J. R. Partington were unable to prepare the hemioxide. The product obtained by following A. Besson's directions is somewhat variable in composition and appears to be a mixture of finely divided amorphous phosphorus with strongly adsorbed phosphorous acid, although, especially when prepared at lower temp., solid hydrogen phosphides may be present. The amount of oxygen present is always much less than is required by the formula P_2O, and hydrogen also is always present, even after prolonged drying over phosphorus pentoxide.

§ 14. Hypophosphorous Acid

In 1816, P. L. Dulong[1] reported the isolation of the salt of *l'acide au minimum d'oxygène*, which he proposed to name *acide hypophosphoreux*, **hypophosphorous acid**, H_3PO_2. It was obtained from the liquid produced when the phosphides of alkaline earths are treated with water. In the following year, H. Rose investigated a whole series of salts of this acid.

P. L. Dulong showed that hypophosphorous acid or its salts are formed by the decomposition of phosphides of the alkaline earths by water ; and H. Rose, by boiling phosphorus with milk of lime, baryta-water, or an aq. or alcoholic soln. of potassium hydroxide. The following process has been recommended—*vide infra*, calcium hypophosphite :

Two kgrms. of quicklime are slaked with about 5 litres of water, and then added to 20 litres of water contained in an iron boiler. Then add about 0·5 kgrm. of phosphorus. Keep the mixture boiling and add more water from time to time to make up for that lost by evaporation. During this process there is a continued evolution of spontaneously inflamed phosphine. When the strong odour of phosphine ceases to be given off, the soln. is filtered and the residue is washed. The residue is composed of the excess of calcium hydroxide and phosphate—about half the phosphorus is converted into phosphate. The soln. and washings are then concentrated, and again filtered to remove a small quantity of calcium carbonate which has been formed by the action of the air on the lime in soln. The concentrated liquid is now evaporated until a pellicle forms, when the calcium hypophosphite crystallizes ; or the heat may be continued, the liquid being constantly stirred, until the salt is obtained in a granular form. A soln. of the calcium hypophosphite is then treated with 1·37 times its weight of oxalic acid ; and the clear filtrate evaporated as required.

J. A. Kendall found it advantageous to mix charcoal with the phosphorus before adding the latter to the milk of lime or other hydrate used. The charcoal or powdered coke is made into a thin cream with water and mixed by heat and agitation with the phosphorus. When cold, the mixture is added to the milk of lime in the usual way. C. A. Wurtz made the hypophosphite by boiling a soln. of barium sulphide with phosphorus; A. Winkler, by the action of phosphine on aq. soln. of the alkali or alkaline earth hydroxides; A. Cavazzi, by the action of phosphine on sulphurous acid in the presence of mercury at 60°–70°: $PH_3+H_2SO_3+Hg=H_3PO_2+H_2O+HgS$; C. A. Wurtz, by the slow oxidation of hydrogen hemiphosphide; A. Michaelis and co-workers, by heating phosphorus tetritoxide in moist air; W. Ipatieff and W. Nikolaieff, by the action of hydrogen, at 250 to 300 atm. press., and 360° to 400°, on lead phosphate; and A. Oppenheim, by heating phosphorus with syrupy phosphoric acid at 200°.

P. L. Dulong filtered the liquid obtained by the action of water on barium phosphide to remove the barium phosphate; added dil. sulphuric acid to precipitate barium sulphate, and evaporated the filtered soln. of hypophosphorous acid at 80° to 90° to a syrupy consistency. J. Thomsen cooled the conc. aq. soln. to 0°, and obtained crystals of the acid. A. Geuther, E. Merck, and C. Marie employed a similar process. G. Lunau obtained a soln. of the acid by treating the calcium salt with oxalic acid. H. Rose treated the barium salt with an excess of sulphuric acid, digested the filtrate with an excess of lead monoxide, and treated the filtered soln. of basic lead hypophosphite with hydrogen sulphide; and, after filtering off the lead sulphide, concentrated the soln. of phosphoric acid by evaporation. C. Marie treated the sodium salt with the calculated amount of sulphuric acid, extracted the hypophosphorous acid by shaking the liquid with absolute alcohol, and evaporated the alcoholic soln. in vacuo. The commercial acid usually contains calcium salts. A. Michaelis and K. von Arend purified the acid by evaporating it on a water-bath, then adding absolute alcohol and dry ether; filtering the liquid from sediment; distilling off the alcohol and ether; and evaporating the residue on a water-bath. G. Heikel purified the acid by adding ammonium oxalate to the aq. soln. The filtered soln. of ammonium hypophosphite was treated with barium carbonate and boiled until the smell of ammonia disappeared. The barium salt was then decomposed by the calculated quantity of sulphuric acid as indicated above.

The early workers described hypophosphorous acid as a colourless, viscid, non-crystallizable liquid; but J. Thomsen was able to induce the crystallization of the syrupy liquid by rubbing the walls of the glass containing vessel with a glass rod at 0°. C. Marie purified the acid by fractional crystallization, and started the crystallization by seeding the syrupy liquid with a crystal of the acid. C. A. Wurtz gave 1·493 for the sp. gr. of the syrup at 18·8°; and A. Geuther, 1·49 at 10°. A. Michaelis and K. von Arend gave 1·4625 for the sp. gr. of the crystals. M. Wien measured the relation between the viscosity and electrical conductivity of aq. soln. of the acid. J. Thomsen said that the crystals gradually melt at ordinary temp. in air, but the liquid solidifies again when surrounded by cold water; he gave 17·4° for the m.p.; while C. Marie gave 26·5° for the m.p. of the acid. The melted acid has a great tendency to undercooling. According to P. L. Dulong, the acid decomposes when heated giving off phosphorus vapour; but H. Rose showed that phosphine and phosphoric acid are the products of decomposition: $4H_3PO_2=2PH_3+2H_3PO_4$. C. Marie said that the thermal decomposition occurs in two phases: Above 100°—and rapidly between 130° and 140°—the reaction is symbolized: $3H_3PO_2=PH_3+2H_3PO_3$; and above 140°—and rapidly between 160° and 170°: $4H_3PO_3=PH_3+3H_3PO_4$. N. R. Dhar found that the decomposition of hypophosphorous acid into phosphine and phosphoric acid is retarded by mild reducing agents. E. Cornec measured the lowering of the f.p. of soln. of hypophosphorous acid when progressively neutralized by sodium hydroxide. The resulting simple V-curve is characteristic of monobasic acids. Similar results were obtained with aq. ammonia in place of the soda-lye. J. Thomsen gave for the heat of formation of the crystallized acid $(3H,P,O_2)=139·950$ to $139·970$

Cals.; 137·550 to 137·660 Cals. for the fused acid; and 139·750 to 139·800 Cals. for the aq. soln. J. Thomsen's value for the heat of fusion is 2·4 Cals.; and for the heat of soln., —0·2 to —0·17 Cal. for the crystals, and 2·2 to 2·14 Cals. for the fused acid. E. Petersen gave 0·713 Cal. for the heat of dilution. P. A. Favre and J. T. Silbermann gave 48·3 Cals. for the heat of oxidation. J. Thomsen found the heat of neutralization for $n\mathrm{H_3PO_2}$aq.+NaOHaq. to be 15·4, 15·2, and 7·6 Cals. for $n=2$, 1, and 0·5 respectively; and for $\mathrm{H_3PO_2}+\frac{1}{2}\mathrm{Ba(OH)_2}$, 15·46 Cals. This is taken to favour the assumption that the acid is monobasic. J. C. Thomlinson attempted to obtain evidence in the chemical constitution of this acid from the thermochemical data. P. A. Favre and J. T. Silbermann gave for the relative thermal eq. of hypophosphorous, phosphorous, and phosphoric acids, respectively, 1; 2·91; 4·36. O. Stelling studied the X-ray spectrum. W. Ostwald found the mol. electrical conductivity of aq. soln. with a mol of hypophosphorous acid in v litres, at 25°, to be

v .	2	4	8	16	32	64	128	256	512	1024
μ .	140	172	207	245	281	312	335	352	361	367
α .	0·360	0·442	0·532	0·630	0·722	0·802	0·861	0·905	0·925	0·9148
K .	0·1012	0·0876	0·0757	0·0670	0·0587	0·0508	0·0417	0·0336	0·0234	0·0154

The values for α, the degree of ionization, and the ionization constant, k, are derived from the mass-law equation $K=\alpha^2(1-\alpha)v$, on the assumption that S. Arrhenius' value, 389, represents the mol. conductivity at infinite dilution. A. D. Mitchell found K to be more nearly constant by writing $K=\alpha^2(1-\alpha)v=0{\cdot}1015-\frac{1}{35}\log v$. I. M. Kolthoff found that the ionization constant increases from $K=0{\cdot}01$ in a 0·001M-soln. to $K=0{\cdot}062$ in 0·05M-soln. at 18°; allowing for the activity of the ions, K increases from 0·020 for 0·001M-soln. to 0·053 for 0·1M-soln. Hypophosphorous acid behaves as a strong monobasic acid, and it can be titrated using methyl orange as indicator. A. D. Mitchell also measured the ionization of hypophosphorous acid in the presence of hydrochloric acid by the hydrolysis of methyl acetate process, and found the results to be in accord with the rate that in a mixture of two electrolytes, each is ionized to the same extent as it would be if present alone in a soln. having the same conc. of ions. W. Ostwald's values for the effect of temp. on the conductivity of N-$\mathrm{H_3PO_2}$ are indicated in Fig. 30. H. Wegelins examined the effect of conc. on the optimum temp. of the conductivity. S. Arrhenius represented the temp. coeff. of the mol. conductivity of soln. with n-gram-equivalent per litre, at 35° by 0·0148 for $n=0{\cdot}001$; 0·0110 for $n=0{\cdot}01$; 0·0058 for $n=0{\cdot}1$; and 0·0041 for $n=0{\cdot}5$. The effect of temp., θ, on the conductivity, λ, can be represented by $\lambda=\lambda_0e^{-0{\cdot}00992(1+0{\cdot}01455\theta)}$, which is a maximum when θ_0 corresponding with λ_0 is 25°. Hence the maximum occurs at 57°. E. Blanc measured the neutralization curve with the progressive addition of sodium hydroxide, and obtained for the ionization constant $K_1=0{\cdot}06$. S. Arrhenius also calculated the heat of ionization to be —3·63 Cals. G. Bredig gave for the transport number 41·8. P. Pascal made observations on the magnetic properties of the acid.

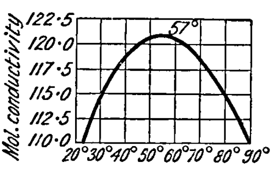

FIG. 30.—The Effect of Temperature on the Molecular Conductivity of Solutions of Hypophosphorous Acid.

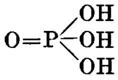
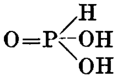
Analyses by P. L. Dulong, A. Geuther, and H. Rose are in agreement with the empirical formula $\mathrm{H_3PO_2}$. C. A. Wurtz, A. Geuther, and J. Thomsen showed that the salts of the acid indicate that hypophosphorous acid is monobasic, and two of the three hydrogen atoms are part of the acid radicle. P. Walden also found the electrical conductivity of the salt in harmony with the same hypothesis. A. L. Ponndorf assumed that the acid contains two hydroxyl groups and one hydrogen atom united to tervalent phosphorus, namely, $\mathrm{H.P(OH)_2}$. This agrees with P. Pascal's observations on the magnetic properties of the acid. Following

A. Lieben, however, it is generally assumed that the phosphorus is quinquevalent in phosphoric, phosphorous, and hypophosphorous acids:



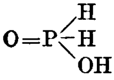
$$\mathrm{O{=}P}{<}\begin{matrix}\mathrm{OH}\\\mathrm{OH}\\\mathrm{OH}\end{matrix}$$

Phosphoric acid (Tribasic).



$$\mathrm{O{=}P}{<}\begin{matrix}\mathrm{H}\\\mathrm{OH}\\\mathrm{OH}\end{matrix}$$

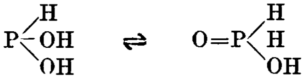
Phosphorous acid (Dibasic).



$$\mathrm{O{=}P}{<}\begin{matrix}\mathrm{H}\\\mathrm{H}\\\mathrm{OH}\end{matrix}$$

Hypophosphorous acid (Monobasic).

The last formula emphasizes the monobasicity of the hypophosphorous acid, and it agrees with O. Stelling's observations on the X-ray spectrum. It is probable that one of the hydrogen atoms is labile, corresponding with the desmotropic change:



$$\mathrm{P}{<}\begin{matrix}\mathrm{H}\\\mathrm{OH}\\\mathrm{OH}\end{matrix} \rightleftharpoons \mathrm{O{=}P}{<}\begin{matrix}\mathrm{H}\\\mathrm{H}\\\mathrm{OH}\end{matrix}$$

because, although dibasic inorganic hypophosphites are not known, yet the so-called *alkyl-phosphinic acids*, formed by oxidizing the secondary phosphines with fuming nitric acid, are to be regarded as derivatives of hypophosphorous acid. *Dimethyl phosphinic acid*, $(CH_3)_2PO.OH$, resembles paraffin, it melts at 76°, and volatilizes without decomposition. A corresponding *diethyl-dithio-phosphinic acid*, $(C_2H_5)_2PS.SH$, is known. The tendency of phosphorus to pass into the $O{=}P{\equiv}$ form is illustrated by the action of heat on this acid, and on its salts, for phosphoric acid and phosphine are produced: $2H_3PO_2{=}OP(OH)_3{+}PH_3$. According to A. Geuther, neither the anhydride, P_2O, nor the chloride, PCl, corresponding with hypophosphorous acid is known. L. Lendle, and G. Schick found that the barium salts of phosphorous acid or of hypophosphorous acid, prepared at high and low temp., reduce silver and mercury salts with very different velocities; and they assumed that there are two different forms of hypophosphite or phosphite. They associated the assumed alteration in the constitution of the hypophosphites with the change in the conductivity which occurs with variations of temp.—Fig. 30, for the active form is obtained at a low temp., the inactive form at a high temp. H. Gorke, however, showed that the active form is contaminated with acid. H. Burgarth, H. Remy, and T. M. Lowry's observations made observations on the electronic structure of hypophosphorous acid, *vide supra*, phosphoric acid.

While C. A. Wurtz[2] said that **hydrogen** in *statu nascendi* reduces hypophosphorous acid to phosphine, A. L. Ponndorf observed no reduction at all in acidic or alkaline soln. C. F. Rammelsberg found that when exposed to **air**, hypophosphorous acid oxidizes to phosphorous acid, and then to phosphoric acid. A. Benrath and K. Ruland observed that hypophosphorous acid is oxidized to phosphorous acid in the presence of ceric sulphate. E. Rupp and A. Finck said that the speed of oxidation of hypophosphorous acid is small in alkaline soln., but increases proportionally with the acidity of the soln. A. Michaelis and M. Pitsch obtained phosphorus tetritoxide (*q.v.*) by the action of **water** on this acid. N. Bakh said that when the reaction $NaH_2PO_2{+}H_2O{=}NaH_2PO_3{+}H_2$ is catalyzed by palladium-black, the quantities of various poisons required per mol of palladous chloride are: potassium cyanide, 1·75 mols; mercuric chloride, 1 mol; thiocarbamide, 1·5 mols; and quinine hydrochloride, over 10 mols. Alkaloids generally have a relatively weak action on catalysts. The poisoning effect is due partly to chemical combination between the palladous chloride and the poison, yielding a compound which cannot be reduced by sodium hypophosphite, and partly to adsorption on the surface of the palladium-black. With colloidal palladium, the effect is one of adsorption, and again a definite number of mols of the poison is required to saturate the surface of the palladium particles and paralyze their action. I. M. Kolthoff, and M. Major studied the oxidation of hypophosphites by **hydrogen dioxide.** P. L. Dulong showed that the acid is oxidized by **chlorine** in aq. soln. I. M. Kolthoff, and F. X. Moerk oxidized soln.

of the acid for analytical purposes by chlorine, and **bromine.** According to E. Rupp and A. Finck, the acid is slowly oxidized by **iodine**, forming phosphorous acid and not phosphoric acid in acidic soln.: $H_3PO_2+I_2+H_2O=H_3PO_3+2HI$; and to phosphoric acid in the presence of an excess of sodium hydrocarbonate: $H_3PO_2+2I_2+2H_2O=H_3PO_4+4HI$. An analytical process for the determination of hypophosphorous and phosphorous acids in a given mixture has been based on these facts. This was studied by I. M. Kolthoff. B. D. Steele found that the speed of oxidation of hypophosphorous acid by iodine in acid soln. is independent of the conc. of the iodine provided there is more than about $0{\cdot}004N$-I_2 present—the limiting value of this conc. varies with the initial conc. of the acid. The reaction is unimolecular with respect to hypophosphorous acid, but it is catalytically accelerated by $H^{\cdot}$-ions. Since $H^{\cdot}$-ions are produced during the course of the reaction, in the absence of any large initial conc. of the acid, the reaction undergoes autocatalytic acceleration. The velocity constant k is 0·043 at 18°, and 0·095 at 25°; it varies within narrow limits with the initial conc. of the hypophosphorous acid and the added acid: $\log k=0{\cdot}1134\theta-5{\cdot}1879$. The rise in the value of k is about 0·031 per 10°. A. D. Mitchell found that the effect of the conc. of the iodine is slight at moderate dilutions, but is relatively large at greater dilutions where the conc. of the I_3'-ion is; and the effect of the hydrochloric and hydriodic acids on the ionization of the hypophosphorous acid should be considered. It is assumed that the oxidation of hypophosphorous acid takes place in two stages. The known facts are explained by assuming that the non-ionized mols. of hypophosphorous acid are in equilibrium with a small proportion of active H_5PO_3-molecules: $H_3PO_2+H_2O\rightleftharpoons H_5PO_3$, which react rapidly with iodine: $H_5PO_3+I_3'\rightarrow H_3PO_3+2H^{\cdot}+3I'$; and the restoration of the equilibrium so displaced is accelerated by $H^{\cdot}$-ions, and forms the measurable reaction $H_3PO_2+H_2O\rightleftharpoons H_5PO_3$. The reaction was studied by M. Boyer and M. Bauzil, and A. Brukl and M. Behr. A. L. Ponndorf observed that no reaction occurs with **hydrochloric acid** at 100°; but A. Michaelis and M. Pitsch obtained phosphorus tetritoxide (*q.v.*), or impure red phosphorus, by the action of this acid—particularly with alcoholic soln. A. L. Ponndorf said that with **hydriodic acid** there is a vigorous reaction: $3H_3PO_2+HI=2H_3PO_3+PH_4I$. W. Ostwald found hypophosphorous acid accelerates the reaction between hydriodic and hypobromous acids. D. Vitali represented the reaction with **potassium iodate**: $KIO_3+H_3PO_2=KH_2PO_2+HIO_3$; and $HIO_3+3KH_2PO_2=3KH_2PO_3+HI$; as well as $5HI+HIO_3=3I_2+3H_2O$; and $3I_2+3KH_2PO_3+3H_2O=6HI+3KH_2PO_4$; the **chlorates** and **bromates** are not reduced. K. A. Hofmann found that in the presence of a trace of osmium tetroxide, a neutral or slightly acid soln. of potassium chlorate oxidizes hypophosphorous acid to phosphoric acid.

According to A. L. Ponndorf, and R. Rother, **sulphur dioxide** acts on hypophosphorous acid, forming sulphur and phosphorous acid; and L. Maquenne said that in aq. soln., there is a momentary formation of hyposulphurous acid before the sulphur separates. O. von Dienes said that sulphur dioxide—gaseous or in aq. soln.—can be reduced to hydrogen persulphide by hypophosphorous acid. C. A. Wurtz observed that when warmed in the presence of conc. **sulphuric acid**, phosphoric acid is produced with the separation of sulphur and the evolution of some sulphur dioxide. A. Gutbier and E. Rohn found that alkaline soln. of **selenious acid** are reduced to selenium, and in acidic soln., to hydrogen selenide; while soln. of **selenic acid** are scarcely affected by hypophosphorous acid. A. Gutbier found that tellurium is precipitated from soln. of **tellurous acid**, and of **telluric acid.** H. Rose found that **nitric acid** oxidizes hypophosphorous acid to phosphoric acid. A. Geuther said that soon after the acid has been added and the soln. is warm, red fumes are given off and the hypophosphorous acid is converted into phosphorous acid; and when the soln. is evaporated, more red fumes are evolved and the phosphorous acid is converted into phosphoric acid. A. Michaelis and M. Pitsch found that a conc. aq. soln. of hypophosphorous acid forms phosphorus tetritoxide (*q.v.*) when treated with **phosphorus trichloride**; and, according to

A. Geuther, the reaction is as follows: $3H_3PO_2+PCl_3=2P(OH)_3+2P+3HCl$. Orthophosphoric acid is also produced, but this probably arises from the action of phosphorus trichloride on phosphorous acid. These results agree with $H.P(OH)_2$ for the formula of hypophosphorous acid. The action of **phosphorus oxychloride** is similar to that of the trichloride, but the reaction is more energetic, and after it has ceased, a fresh reaction may be produced by heating the mixture to 100°. The two stages may be represented as follow: (i) $6H_3PO_2+3POCl_3=3HPO_3+2P(OH)_3+4P+9HCl$; (ii) $2P(OH)_3+3POCl_3=3HPO_3+2PCl_3+3HCl$. The former reaction is probably the resultant of the following: $6H_3PO_2=2PH_3+4P(OH)_3$; followed by $4P(OH)_3+3POCl_3=3HPO_3+2PCl_3+3HCl+2P(OH)_3$; and by $2PH_3+2PCl_3=4P+6HCl$. Hypophosphorous acid thus behaves like a mixture of phosphine and phosphorous acid; and when it is heated to 110°–115°, it is decomposed into these substances; but when the temp. reaches 250° the phosphorous acid itself decomposes. The action of **phosphorus pentachloride** on hypophosphorous acid is energetic, red phosphorus being deposited; but after sufficient of the pentachloride has been added, and the mixture has been heated, nothing remains but phosphorus oxychloride and phosphorus trichloride. The reactions are probably as follow: $3H_3PO_2+6PCl_5=6POCl_3+PCl_3+2P+9HCl$; followed by $6H_3PO_2+6POCl_3=6HPO_3+2PCl_3+4P+12HCl$; $6HPO_3+12PCl_5=18POCl_3+6HCl$; and $6P+9PCl_5=15PCl_3$; the resultant reaction being $H_3PO_2+3PCl_5=2POCl_3+2PCl_3+3HCl$. A. Michaelis and M. Pitsch said that **acetic anhydride** withdraws the elements of water from hypophosphorous to furnish phosphorus tetritoxide (*q.v.*), and **acetyl chloride** gives the same product: $9H_3PO_2+12CH_3COCl=H_3PO_4+2P_4O+12CH_3COOH+12HCl$, as well as: $5H_3PO_2+6CH_3COCl=H_3PO_3+P_4O+6CH_3COOH+6HCl$; and there is a side reaction, $4H_3PO_2=H_3PO_4+H_3PO_3+H_2O+P_2H_4$. J. Ville studied the action of hypophosphorous acid on various **aldehydes**; R. Fosse, on aromatic **alcohols**, aldehydes, and **ketones**; and C. Marie, on **acetone.** J. Mai found that hypophosphorous acid readily converts the **diazo-salts** into hydrocarbons. H. W. Jones found that the acid dissolves **strychnine** and **morphine.** Hypophosphorous acid attacks **glass** and **porcelain** more rapidly than phosphoric acid.

According to F. Loessner, when a soluble hypophosphite is heated with a conc. soln. of **alkali hydroxide,** the salt is oxidized: $NaH_2PO_2+NaOH=Na_2HPO_3+H_2$. The reaction is unimolecular, and the velocity is nearly doubled by a rise of temp. from 92°–100°. Eq. proportions of sodium and potassium hydroxides have the same influence. The velocity constant, *k*, increases with increasing conc. of alkali-lye, but not proportionally; thus with

	NaOH				KOH	
	1·23*N*-	2·43*N*-	3·94*N*-	4·90*N*-	2·4*N*-	4·42*N*-
k . .	0·00041	0·00152	0·00516	0·00983	0·00166	0·00787

According to P. L. Dulong, and H. Rose, hypophosphorous acid reacts with some metal oxides producing hypophosphites; others are reduced to metals; others to hydrides. Thus, H. Rose represented the reaction with **copper sulphate:** $Ba(H_2PO_2)_2+4CuSO_4+4H_2O=2H_3PO_4+BaSO_4+3H_2SO_4+4Cu$; on the other hand, C. A. Wurtz, C. F. Rammelsberg, and W. Muthmann and F. Mawrow said that with a soln. of cupric sulphate, copper hydride is formed; or else copper accompanied by the evolution of hydrogen if the temp. exceeds the decomposition temp. of the hydride. The reaction was studied by M. Major. S. Ramachandran showed that the reduction occurs only when the soln. is distinctly acid. According to A. Sieverts, if an excess of the hypophosphite be employed, the precipitate, when heated, gives off hydrogen and forms a red spongy mass of copper; on the other hand, if an excess of the copper salt be present, a brownish-yellow precipitate is formed, which, on boiling, furnishes a crystalline powder of copper. In all cases, cuprous salts are produced as an intermediate stage in the reduction. In the reaction between copper sulphate and hypophosphorous acid, the quantity of hydrogen set free does not depend upon the amount of cuprous hydride formed, but rather on the amount of hypophosphorous acid present. The evolution of gas is caused by the copper-sponge resulting from the decomposition of the hydride, and the action continues so long as any hypophosphorous acid remains undecomposed. E. J. Bartlett and W. H. Merrill consider that the action is due to the formation of a cupric hydride which acts catalytically on the hypophosphorous acid, oxidizing it to phosphorous acid and liberating hydrogen: $H_3PO_2+H_2O=H_3PO_3+H_2$, just as palladium hydride, according to R. Engel, oxidizes barium hypophosphite to the phosphite with the evolution of hydrogen by a continuous action without appreciably affecting the hydride. If a syrupy soln. of hypophosphorous acid be treated with cupric hydride, a mixture of phosphine and hydrogen is given off which is not spontaneously inflammable. A. Sieverts and F. Loessner consider that the metal and not the hydride is the catalyst, since palladium precipitated by carbon monoxide is virtually free from hydrogen, and yet it decomposes hypophosphites. The reaction is discussed in connection with copper hydride—**3**. 21, 6. J. B. Firth and J. E. Myers showed that with an acidic soln. of copper sulphate, sodium hypophosphite produces a substance which appears to be a mixture of cuprous oxide, hydride, and phosphate. A. D. Mitchell showed that with cupric chloride, the first stage of the reduction results in the change of hypophosphorous acid *molecules* to the active form, provisionally formulated as H_5PO_3; this change is catalyzed by hydrogen ions. In dil. copper soln. two succeeding reactions have been detected: (i) an equilibrium in which the copper ion and the active hypophosphorous acid give a complex ion ($X^{\cdot\cdot}$) and hydrogen ions, which therefore repress the reaction: $H_5PO_3+2Cu^{\cdot\cdot}=X^{\cdot\cdot}+2H^{\cdot}$; and (ii) a direct reaction between the complex and chloride ions: $X^{\cdot\cdot}+2Cl'=Cu_2Cl_2+H_3PO_3$.

P. L. Dulong observed that hypophosphorous acid reduces soln. of **silver salts**. The reaction was studied by M. Major, and C. F. Rammelsberg. A. Sieverts and co-workers said that the reaction with silver nitrate may be attended by the evolution of hydrogen: $2NaH_2PO_2+2AgNO_3+4H_2O=2H_3PO_4+2NaNO_3+2Ag+3H_2$; or hydrogen may not be evolved: $NaH_2PO_2+4AgNO_3+2H_2O=H_3PO_4+NaNO_3+3HNO_3+4Ag$. There are complications owing to the reduction of the anion. A soln. of silver phosphate is reduced to the metal by hypophosphorous acid; and even in ammoniacal soln., the precipitate is silver, not silver suboxide; and there is no evidence of the formation of silver hydride reported by E. J. Bartlett and W. F. Rice—*vide* **3**. 22, 7. A. D. Mitchell found that in the reduction of silver nitrate, the reaction, $2AgNO_3+H_3PO_2+H_2O=2Ag+2HNO_3+H_3PO_3$, is also attended by $4AgNO_3+H_3PO_2+2H_2O=4Ag+4HNO_3+H_3PO_4$. He found that hypophosphorous acid reduces silver nitrate at the same rate as, *ceteris paribus*, it reduces iodine, mercuric chloride, or cupric chloride. This rate is independent of the conc. of the substance undergoing reduction, provided it exceeds a definite value, which is $N/50$ in the case of silver nitrate, and is ascribed to a change involving the formation of an active form of the acid. P. L. Dulong observed that soln. of **gold salts** are reduced by hypophosphorous acid; and, added A. Sieverts, the precipitate slowly oxidizes a boiling soln. of the acid, and hydrogen is evolved. The reaction was also studied by M. Major. H. Rose found that soln. of **mercuric chloride** are reduced to mercurous chloride and to mercury. The reaction was studied by A. Sieverts. The oxidation of hypophosphorous to phosphorous acid proceeds relatively quickly, $H_3PO_2+2HgCl_2+H_2O=H_3PO_3+Hg_2Cl_2+2HCl$; and that of phosphorous to phosphoric acid relatively slowly, $H_3PO_2+4HgCl_2+2H_2O=H_3PO_4+2Hg_2Cl_2+4HCl$. In the first stage of the oxidation, A. D. Mitchell observed that the concentration of mercuric chloride appeared to have no influence on the reaction velocity except when very dil. The reaction was accelerated by the addition of hydrochloric acid. It was therefore auto-catalytic, owing to the hydrochloric acid produced The initial velocity was approximately proportional to the product of the concentrations of the hydrogen ions and the hypophosphorous acid. It was therefore concluded that the oxidation to phosphorous acid involved two successive reactions: the first, of measurable velocity, in which the mercuric chloride took no part, and the second, of relatively great velocity, in which the mercuric chloride played a part. As in the case of iodine (*vide supra*), it was found that the measurable velocity of the reaction between hypophosphorous acid and mercuric chloride, if the soln. are not too dil., is independent of the conc. of the latter, as in the analogous reaction with iodine, and is due to the re-establishment of equilibrium between hypophosphorous acid *molecules* and the hypothetical "active" form, H_5PO_3. This change is catalyzed by hydrogen ions, and the reaction is therefore autocatalytic. This is followed by a rapid reaction which can only be detected at low concentrations. The evidence is strong, but not quite conclusive that this reaction takes place between one mol of mercuric chloride (and not of its ions or possible complexes) and two mols of "active" hypophosphorous acid. R. Engel found that the precipitation of metal from **stannous salts,** and **lead salts** by hypophosphorous acid and palladium interferes with the catalytic activity of the palladium; but the mixture completely decomposes **antimony salts** at ordinary temp.; and likewise also **bismuth salts.** W. Muthmann and F. Mawrow showed that soln. of bismuth salts give a precipitate of bismuth. **Arsenic salts** give a brown coloration with hypophosphorous acid, and on that account, E. Deussen, and E. Rupp and E. Muschiol recommended calcium hypophosphite as a precipitant for arsenic in detecting that element in soln. of arsenic salts. I. M. Kolthoff, and M. Major studied the oxidation of hypophosphites by soln. of **potassium dichromate.** A. D. Mitchell indicated that the reaction with chromic acid is probably the resultant of a slow, unimolecular reaction: $H_3PO_2+Cr_2O_7''=H_3PO_3+Cr_2O_6''$, and the fast reaction: $2H_3PO_2+Cr_2O_6''+8H^{\cdot}=2H_3PO_3+2Cr^{\cdot\cdot\cdot}+4H_2O$, *vide supra.* The velocity constants vary inversely as the 7th power of the initial conc. of the chromic acid. According to A. Winkler, hypophosphorous acid and hypophosphites give a blue coloration or a blue precipitate with **ammonium molybdate;** but E. J. Millard could not obtain other than a faint coloration, if at all, with acidic, neutral, or alkaline soln. of the molybdates. He found that the addition of a small quantity of sulphurous acid renders the test a most delicate one, and one which the ordinary nitric acid soln. of ammonium molybdate answers well. Phosphates, pyrophosphates, and phosphites do not give the reaction when similarly treated. In pure soln. it is possible to detect 1 part of hypophosphorous acid in 2000. C. Ebaugh and E. F. Smith observed that the molybdic acid is reduced to the pentoxide, Mo_2O_5; and that the method is untrustworthy for quantitative analysis. O. W. Gibbs prepared complex hypophosphatomolybdates—*vide infra.* F. X. Moerk obtained colour reactions with **sodium tungstate** and hypophosphorous acid in the presence of sodium sulphite. O. W. Gibbs prepared complex hypophosphatotungstates. L. P. de St. Gilles, and I. M. Kolthoff, found that **potassium permanganate** oxidizes hypophosphorous acid completely to phosphoric acid. L. Amat found that the oxidation proceeds more quickly the more conc. the soln., the more acidic the soln., and the higher the temp.; at ordinary temp., and in dil. soln., the oxidation is incomplete. If the soln. be too hot, some permanganate may be decomposed without interaction with the hypophosphorous acid. The reaction was studied by I. M. Kolthoff. M. Major, and A. Sieverts found that reduced **iron** readily dissolves in a hot soln. of sodium hypophosphite; **ferric salts** are reduced to the ferrous state; and ferric alum reacts at the temp. of the water-bath, while phosphorous acid is not attacked after several hours. M. Major studied the reduction of iron alum by hypophosphites. A. D. Mitchell found that a considerable error is caused by the presence of hypophosphorous acid when ferrous salts are titrated by potassium dichromate. This is tentatively ascribed to the ferrous salt acting as "inductor" in the oxidation of hypophosphorous acid by chromic acid, probably in virtue of the transient formation of the quinquevalent chromium compound, which has been found by other workers also to be exceedingly reactive. He also found that finely-divided **nickel** and **cobalt** behave like palladium (*vide infra*) in oxidizing soln. of the hypophosphites, with the evolution of hydrogen. Soln. of **cobalt salts** and of **nickel salts** are not reduced by hypophosphorous acid, but the metals reduced by hydrogen oxidize cold soln. of sodium hypophosphite to phosphite. Soln. of **platinum salts** are not reduced by hypophosphites, even when boiling. A. Atterberg, and F. Loessner showed that the gradual darkening of the soln. of platinic chloride is due to the formation of platinous chloride. F. Loessner, and M. Major showed that the oxidation of the hypophosphite which occurs in the presence of finely-divided **platinum** is due to the occluded oxygen. C. A. Wurtz, F. Loessner, and A. Sieverts found soln. of **palladium salts** are reduced by hypophosphorous acid in the cold, and, according to the former, some hydrogen is given off; F. Loessner represented the reaction: $2PdSO_4+H_3PO_2+2H_2O=2Pd+H_3PO_4+2H_2SO_4$. R. Engel said that palladium precipitated from a soln. of the chloride by means of hypophosphorous acid retains a small quantity of hydrogen. The quantity of hydrogen evolved is much greater than the quantity which could be liberated from a palladium hydride. When spongy **palladium** is brought in contact with hypophosphorous acid, the latter is rapidly converted into phosphorous acid, and hydrogen is liberated. The palladium seems to retain its activity indefinitely, and 0·5 grm. of the metal decomposed the acid obtained from 500 grms. of barium hypophosphite. The reaction is not arrested by press. It is probable that the palladium removes an atom of hydrogen from the hypophosphorous acid, but quickly loses it, whilst the residue of the acid interacts with the water, combining with hydroxyl, and liberating another atom of hydrogen. The reaction was studied by F. Loessner, and M. Major—the latter represents the reaction $H_3PO_2+H_2O=H_2+H_3PO_3$. Water is necessary for the reaction; alcohol will not do. The presence of sodium hydrocarbonate favours the reaction, while alkali or sulphuric acid retards the reaction. According to A. Sieverts, even a cold soln. of sodium hypophosphite is oxidized by precipitated palladium to phosphite, and even further on boiling. Alcoholic sodium hypophosphite does not react with palladium.

§ 15. The Hypophosphites

The hypophosphites are obtained by dissolving the bases in an aq. soln. of the acid ; by boiling phosphorus with alcoholic potash ; or by boiling phosphorus with the hydroxides of the alkalies or alkaline earths in aq. soln. Many of the hypophosphites are obtained by treating the barium salt with the sulphates of the other metals, or the calcium salt with the carbonates. The solid salts are usually stable in air. When heated, the salts of sodium, thallium, lithium, magnesium, zinc, cadmium, calcium, strontium, barium, manganese, and lead give off hydrogen and phosphine, and leave pyro- or meta-phosphates behind ; the cobalt and nickel salts form the metaphosphate and phosphide ; and the uranium salt gives a mixture of meta- and pyro-phosphates and phosphide. The hypophosphites are nearly all fairly soluble in water, and the alkali salts are also soluble in alcohol. If the aq. soln. are boiled out of contact of air, they suffer no change, but in air, they are oxidized to phosphites and phosphates ; when heated with alkalies, they form phosphites and phosphates with the evolution of hydrogen. According to C. F. Rammelsberg,[1] the hypophosphites are all decomposed by heat furnishing pyrophosphate and metaphosphate in the molar proportion 1 : 1 with the sodium and thallium salts ; 2 : 1 with the magnesium, zinc, and manganese salts ; 3 : 1 with calcium, strontium, cadmium, and cerium salts ; 4 : 1 with the lead salt ; and 6 : 1 with the barium salt. The nickel and cobalt salts yield metaphosphate and phosphide ; and the uranyl salt, pyrophosphate, metaphosphate, and phosphide.

H. Rose studied mainly the gaseous products and his work on the solid product was incomplete. C. F. Rammelsberg found that the gaseous products of the decomposition of hypophosphites being always a mixture of hydrogen and phosphine, the inflammability of the gas is of no importance, and seems to vary according to circumstances. The separation of phosphorus is due to the process itself, and does not depend on the decomposition of phosphine, for very often phosphorus appears at the beginning of the process, when the temp. is not sufficient for the decomposition of phosphine.

According to G. Polk,[2] P. Schulz, and M. Paquelin and L. Joly, there is no evidence that the hypophosphites exert the slightest toxic effect. They pass through the system unchanged. According to T. Panzer, experiments with dogs showed that calcium hypophosphite is rapidly eliminated from the system and passes unaltered into the urine. The presence of hypophosphite may be generally detected after half an hour, and no more can be found after 24 hrs. The other organs, blood, and fæces are practically free from hypophosphite. In human beings the elimination seems to take a little longer. In case of a supposed poisoning by phosphorus, inquiries should be made as to whether the person has taken any hypophosphite shortly before death ; should this be proved, the presence of phosphorous acid in the urine or intestinal canal counts for nothing. As previously indicated, the hypophosphites have been tried as explosives but without any particularly useful results. The *ferri hypophosphis*, *sodii hypophosphis*, and *calcii hypophosphis* of the pharmacopœia are respectively iron, sodium, and calcium hypophosphites.

P. L. Dulong,[3] C. F. Rammelsberg, and C. A. Wurtz prepared **ammonium hypophosphite,** $(NH_4)H_2PO_2$. It is obtained by treating barium hypophosphite with ammonium sulphate, evaporating the filtrate to dryness, and crystallizing the product from its soln. in hot water or alcohol. A. Michaelis and K. von Arend treated the acid or the calcium or barium salt with ammonium carbonate in excess, and evaporated the filtrate as before. The salt was analyzed by C. A. Wurtz, and A. Michaelis and K. von Arend. C. F. Rammelsberg measured the crystal angles, and J. Beckenkamp gave for the axial ratios of the rhombic bipyramidal crystals $a:b:c=0·5276:1:1·5137$; and C. F. Rammelsberg, $0·339:1:0·665$. The large, tabular crystals were found by C. A. Wurtz to melt at about 200° without loss of water, but at 240°, water and spontaneously inflammable phosphine are given off, and, according to H. Rose, ammonia is also evolved. C. F. Rammelsberg represented the reaction : $7(NH_4)H_2PO_2=H_4P_2O_7+2HPO_3+H_2O+7NH_3+3PH_3+2H_2$. The crystals are less deliquescent than those of the potassium salt. H. Stamm found that the conc. aq. soln. is not changed by the introduction of ammonia. P. L. Dulong found that salt to be freely soluble in alcohol. A. Michaelis and K. von Arend obtained phosphorus tetritoxide by treating the salt with acetic anhydride.

According to A. P. Sabanéeff, **hydroxylamine hypophosphite,** $(NH_3OH)H_2PO_2$, is formed when the barium salt is treated with hydroxylamine hydrosulphate only in an atm. of carbon dioxide because the aq. soln. of the salt is so easily oxidized on exposure to air ; the filtered soln. is evaporated for crystallization without raising the temp. K. A. Hofmann and V. Kohlschütter mixed potassium hypophosphite and hydroxylamine chloride so as to keep the soln. acidic; the product was extracted with hot absolute alcohol, and precipitated from that soln. with ether. The acicular crystals are very hygroscopic ; and they can be preserved in suitable vessels without change. A. P. Sabanéeff found that when the salt is heated, it begins to decompose at about 60°, and fusion occurs at about 92°, forming a transparent mass which detonates at a still higher temp. The salt is freely soluble in water ; and the aq. soln. exhibits the reactions of both hydroxylamine and hypophosphorous acid ; it reduces cold, alkaline soln. of copper salts, and gives no precipitate with barium chloride. The salt is isomeric with ammonium phosphite.

C. F. Rammelsberg prepared **lithium hypophosphite,** $LiH_2PO_2.H_2O$, by double decomposition with soln. of the barium salt and of lithium sulphate. The soln. yields small, colourless, transparent, prismatic crystals belonging to the monoclinic system, and with the axial ratios: $a:b:c=0{\cdot}623:1:1{\cdot}952$, and $\beta=79°\ 52'$. The salt is anhydrous after drying at 200°; if confined over conc. sulphuric acid, it loses one-third of its water of crystallization; and when heated, it decomposes: $9LiH_2PO_2=2Li_4P_2O_7+LiPO_3+4PH_3+2H_2+H_2O$. The salt is freely soluble in water; and when heated with nitric acid, and evaporated, lithium metaphosphate is formed. P. L. Dulong, and H. Rose prepared **sodium hypophosphite,** $NaH_2PO_2.H_2O$. It can be obtained by double decomposition with the calcium salt and sodium carbonate, and evaporating the alcoholic soln. in vacuo. C. F. Rammelsberg prepared it by double decomposition with the barium salt and sodium carbonate, or by treating the acid with sodium carbonate. The aq. soln. can be evaporated to dryness over conc. sulphuric acid. W. Engelhardt described the preparation of the salt. L. C. Marquart, and H. Trommsdorff noted explosions may occur when the soln. is evaporated on the water-bath, or sand-bath.

The commercial salt can be purified by converting it into the barium salt, which is then treated with sodium sulphate. The filtrate is then treated with alcohol and ether to precipitate any calcium hypophosphite which may be present. The filtrate was then evaporated for the sodium salt. J. Beckenkamp found that the monoclinic prisms of the hydrated salt have the axial ratios $a:b:c=0{\cdot}8199:1:2{\cdot}2320$, and $\beta=123°\ 16'$. The salt was found by C. F. Rammelsberg to lose about half its water of crystallization, over conc. sulphuric acid; and at 200° it is almost anhydrous. When heated to a higher temp. H. Rose noted that spontaneously inflammable phosphine is emitted; and C. F. Rammelsberg represented the reaction: $5NaH_2PO_2=Na_4P_2O_7+NaPO_3+2PH_3+2H_2$. The salt is deliquescent in air, and, added H. Rose, rather less so than the potassium salt. J. Thomsen measured the heat of formation from base and acid (*q.v.*). S. Arrhenius found the heat of ionization to be —196 cals. at 35°. P. L. Dulong found the salt to be freely soluble in water, and in alcohol; and when evaporated with nitric acid, C. F. Rammelsberg obtained sodium metaphosphate. According to A. Cavazzi, mixtures of hypophosphites and nitrates are powerful explosives: $NaH_2PO_2+2NaNO_3=Na_3PO_4+H_2O+NO_2+NO$; and A. Berg and L. Cari-Mantrand obtained explosives from mixtures of hypophosphites and chlorates. A mixture of equal parts of barium hypophosphite and potassium chlorate, previously dried at 100°, burns in the open air with great rapidity, producing a feeble report; but when at all confined, as, for instance, in a screw of paper, a sharp detonation results. An electric spark readily fires the mixture; and it is, moreover, very sensitive to shocks and friction, so that great care must be observed in its preparation. A mixture of the explosive with magnesium powder burns very rapidly and with dazzling brilliancy; and as no special contrivance is needed for its combustion, it might be employed as a flashlight for photographic purposes. As the powder is so readily fired by an electric spark, it might advantageously replace mercuric fulminate. It is much cheaper than the latter, and its two components, which need be mixed only when required, are perfectly harmless when separate. A mixture of syrupy sodium hypophosphite and powdered sodium chlorate in some respects resembles nitroglycerol. A drop when heated on metal foil liquefies, boils, and finally, when quite dry, explodes with great violence, generally perforating or deeply indenting the foil. Trials with other hypophosphites did not yield good results. A. Gutmann observed no reaction between sodium hypophosphite and a cold or boiling soln. of sodium thiosulphate—this appears strange in view of the reducing action of the hypophosphite in acidic soln. Aq. soln. of sodium hypophosphite are oxidized under the influence of spongy palladium or palladium black, but not by the wire or foil. The reaction with the greater velocity is symbolized: $NaH_2PO_2+H_2O=NaH_2PO_3+H_2$, so that hydrogen is evolved during the oxidation. The oxidation to phosphate, $NaH_2PO_3+H_2O=NaH_2PO_4+H_2$, proceeds by a slower reaction. N. Bakh studied the poisoning of the catalyst

—palladium—in the reaction, $NaH_2PO_2+H_2O=NaH_2PO_3+H_2$, where the progress of the reaction is measured by the vol. of hydrogen evolved, and the cessation of the evolution of hydrogen shows that complete poisoning has occurred. Each mol of palladous chloride requires 1·75 mols of potassium cyanide, 1·5 mols of thiourea, one mol of mercuric chloride, or over 10 mols of quinine hydrochloride. The poisoning is due partly to the formation of a compound of palladous chloride with the poison which cannot be reduced by the hypophosphite, and partly to the adsorption of the poison by palladium black which cannot then act as a catalyst. With colloidal palladium, the poisoning effect is due to the binding of the mols of the poison on the surface of the palladium particles. H. Stamm found that the sat. aq. soln. gives a precipitate when ammonia is added.

P. L. Dulong prepared **potassium hypophosphite,** KH_2PO_2, in 1816, but T. von Grotthus, and L. Sementini obtained it from the soln. obtained by boiling alcoholic potash-lye with phosphorus, but they mistook the product for a phosphide. H. Rose made it by double decomposition with the calcium salt and potassium carbonate, and C. A. Wurtz, with the barium salt and potassium sulphate. In both cases the filtrate was evaporated to dryness, the product extracted with alcohol, and the alcoholic soln. evaporated in vacuo. H. Rose extracted it from the soln. obtained by boiling phosphorus with potash-lye. The liquid was left to evaporate slowly in air so that the potassium hydroxide may be converted into carbonate. The residue was leached with alcohol, and the alcoholic soln. evaporated in vacuo. The liquid obtained by boiling phosphorus with alcoholic potash-lye can be used; this is decanted, and, if necessary, it is mixed with alcohol to redissolve the salt, which may have crystallized out. Powdered potassium hydrocarbonate is added to convert the hydroxide into carbonate. The soln. is then treated as before. P. L. Dulong found the salt to be more deliquescent than calcium chloride. C. A. Wurtz said that the crystals are hexagonal plates which do not lose weight at 100°, but when heated in a closed vessel give off spontaneously inflammable phosphine, and leave potassium pyrophosphate. C. F. Rammelsberg represented the reaction: $5KH_2PO_2=K_4P_2O_2+KPO_3+2PH_3+2H_2$. L. Sementini said that when the salt is heated, it burns in air with a yellow flame; and detonates vigorously when evaporated with nitric acid. H. Rose found that when boiled with potash-lye, hydrogen is given off and potassium phosphite is formed, and in conc. soln., potassium phosphate. C. A. Wurtz found the salt to be freely soluble in aq. alcohol, less soluble in absolute alcohol, and insoluble in ether. V. Bayerle found that the polarization curve of a soln. of potassium hypophosphite indicates that the soln. is decomposed at the same temp. as that at which potassium ions are deposited; this is taken to show that phosphorus ions are not split off. According to K. A. Hofmann and V. Kohlschütter, **potassium hydroxylamine hypophosphite,** $K_2(NH_2OH)_3(H_2PO_2)_2$, is obtained by neutralizing phosphorous acid with ammonia, then adding four times the quantity of ammonia and two mol. parts of hydroxylamine hydrochloride to one part of the acid; after remaining one hour, the soln. is precipitated with alcohol and the product recrystallized from absolute alcohol. It is also obtained by heating normal ammonium phosphite with a soln. of hydroxylamine hydrochloride in absolute ethyl alcohol and dissolving out the excess of hydroxylamine hydrochloride from the product by warming it with methyl alcohol. It crystallizes in slender, white needles, and at once reduces Fehling's soln. and ammoniacal silver nitrate.

According to H. Rose, the blue soln. of cupric hydroxide in cold hypophosphorous acid may remain unaltered for a long time; and if very dil., it may even be heated without decomposition. If the soln. be evaporated in vacuo at a low temp., the copper is completely reduced as soon as the liquid is highly concentrated C. A. Wurtz found that the soln. obtained by double decomposition of barium hypophosphite and copper sulphate at about 60° precipitates copper hydride—*vide supra.* Once blue crystals of **copper hypophosphite,** $Cu(H_2PO_2)_2$, were obtained; they decomposed abruptly at 65°. According to R. Engel, this salt may be obtained by mixing soln. of barium hypophosphite and cupric sulphate, and adding alcohol to the clear liquor. It forms a brilliant, white precipitate of the composition $Cu(H_2PO_2)_2$, and is somewhat stable both in the solid state and in soln. The solid explodes suddenly at about 90° ; a dil. soln. can be boiled without decomposing. Precipitated palladium decomposes cupric hypophosphite soln. in accordance with the following equation: $Cu(H_2PO_2)_2+2H_2O=Cu+2H_3PO_3+H_2$, and copper hydride is not formed. If, however, an aq. soln. of the salt is boiled, brown cuprous hydride is first precipiated and rapidly splits up into hydrogen and copper. In the first phase of the reaction, hypophosphorous acid is formed, but is slowly oxidized by the copper at about 100°, whereas with palladium this oxidation takes place at the ordinary temp. G. T. Morgan and F. H. Burstall prepared **copper bisethylenediaminohypophosphite,** $[Cu(en)_2](H_2PO_2)_2$, by adding a soln. of barium hypophosphite to onc of copper sulphate and ethylenediamine, and crystallizing the filtrate. The hygroscopic product decomposes rapidly at 115°. A. Gutbier found that dil. hypophosphorous acid gives a white precipitate of **silver hypophosphite** when added to soln. of silver nitrate; if warmed, the salt decomposes rapidly with the separation of silver. No gold hypophosphite has been made—*vide supra* for the action of hypophosphorous acid on the salts of copper, silver, and gold.

H. Rose prepared **calcium hypophosphite,** $Ca(H_2PO_2)_2$, by boiling phosphorus with milk of lime, replacing the water which evaporates from time to time. When the smell of phosphine is no longer perceptible, the filtrate is freed from an excess of lime by the passage of carbon dioxide, and gently warming the mixture to decompose any hydrocarbonate; the filtered soln. is evaporated either in vacuo over conc. sulphuric acid, or in air at a gentle heat—in the latter case, some calcium phosphate is formed—*vide supra*, hypophosphorous acid. C. A. Wurtz, G. Janssen, W. Engelhardt, and L. Berlandt employed a similar process. J. Bachmann decomposed calcium phosphide by boiling water, and after digesting the mixture for some time extracted the hypophosphite as in H. Rose's process. J. F. Martenson employed a similar process. Analyses of the salt were made by H. Rose, C. A. Wurtz, J. Bachmann, and C. F. Rammelsberg. The salt is anhydrous. H. Rose said that the crystals are colourless, rectangular prisms with terminal faces obliquely inclined to the two broad lateral faces; C. F. Rammelsberg gave for the axial ratios of the monoclinic prisms $a:b:c=0\cdot8693:1:1\cdot200$, and $\beta=75° 12'$; and J. Schabus, $1\cdot1963:1:1\cdot3854$, and $\beta=104° 48'$. The crystals became tabular by the extension of the (001)-face; twinning occurs about the (001)-face; and the cleavage on the (001)-face is perfect. The plates are transparent and flexible, and undergo no change on exposure to air. According to J. Bachmann, the crystals have a nauseous, bitter taste. C. A. Wurtz found that the crystals do not lose any water at 100°, but, according to H. Rose, the crystals decrepitate when heated to redness in a retort, and give off first water, then spontaneously inflammable phosphine; C. F. Rammelsberg represented the reaction: $7Ca(H_2PO_2)_2=3Ca_2P_2O_7+Ca(PO_3)_2+6PH_3+4H_2+H_2O$. A. Michaelis gave a similar equation. When heated with nitric acid, the crystals form calcium metaphosphate; and J. Bachmann found that the salt inflames when a small quantity of fuming nitric acid is poured on it; it detonates when admixed with potassium chlorate and quartz; and instantly reduces silver nitrate. H. Rose said that with boiling potash-lye it forms phosphite, but no phosphate; and that the salt is insoluble in conc. alcohol, and sparingly soluble in dil. alcohol. C. A. Wurtz, and H. Rose found that 100 parts of water dissolve 16·7 parts of salt at ordinary temp., and not much more in hot water. G. Janssen said that a soln. of calcium hypophosphite forms carbonate and phosphate when exposed to air; that sulphur, selenium, and tellurium also decompose it into phosphite, then into phosphate, with formation of calcium sulphide, selenide, or telluride respectively. Boron, silicon, and carbon decompose it by heat; calcium borate, silicate, or carbonate is formed, and phosphorus evolved as vapour. Hydrogen decomposes it into phosphate and phosphine. Hydrochloric, hydriodic, hydrobromic, and hydrofluoric acids decompose it into phosphate, phosphine, and a haloid salt. Nitric acid converts it into phosphate, nitrogen peroxide being evolved. The alkaline bases decompose it into phosphate and phosphide. The alkaline carbonates when boiling, and the alkaline sulphates in the cold, transform it into an alkaline hypophosphite and calcium carbonate or sulphate. It precipitates metallic gold from its soln. In a soln. of silver nitrate it produces a white precipitate, which rapidly turns brown; if the hypophosphite be added in excess in the cold, it reduces the silver to the metallic state after some time; by the aid of heat the reduction is more rapid. In a dil. soln. of mercuric chloride, it produces a crystalline precipitate of mercurous chloride. If added in excess it reduces the mercury to the metallic state. From a soln. of copper sulphate it precipitates the oxide, which a continued ebullition reduces to the metallic state.

P. L. Dulong made **strontium hypophosphite,** $Sr(H_2PO_2)_2$, by adding the phosphide to water, and evaporating the filtered liquid to the crystallizing point. H. Rose boiled phosphorus with strontia-water until no more phosphine was evolved; the soln. was filtered from the phosphate produced at the same time, evaporated over sulphuric acid in vacuo; and the residue dissolved in hot water and cooled for crystallization. C. A. Wurtz employed a similar process. Instead of strontia-water, a soln. of strontium sulphide, which generally contains more sulphur than corresponds with the monosulphide, can be used; it acts in the cold. The phosphorus absorbs the excess of sulphur, forming a compound which is broken down by water into hydrogen sulphide and hypophosphorous acid. If heat be applied, there is evolved a mixture of spontaneously inflammable phosphine, hydrogen, and, maybe, a little hydrogen sulphide. The soln. contains strontium hypophosphite, and strontium hydrosulphide which is not decomposed by the phosphorus. The hydrosulphide is decomposed either by lead carbonate or dil. sulphuric acid. The filtered liquid is then evaporated for the strontium salt as before. C. F. Rammelsberg made the salt by dissolving strontium carbonate in hypophosphorous acid, and evaporating the liquor at ordinary temp. According to C. A. Wurtz, the salt appears in masses of tabular crystals and plates which do not lose weight at 100°; C. F. Rammelsberg said the salt is monohydrated, and becomes anhydrous at 200°. H. Rose found that when heated to a higher temp. it gives off spontaneously inflammable phosphine, and C. F. Rammelsberg, and A. Michaelis represent the reaction by an equation similar to that employed for the calcium salt. P. L. Dulong said that the salt is freely soluble in water; and C. A. Wurtz, soluble in alcohol. P. L. Dulong, H. Rose, C. F. Rammelsberg, and C. A. Wurtz prepared **barium hypophosphite,** $Ba(H_2PO_2)_2.H_2O$, by processes similar to those which they employed for the strontium salt. H. Rose obtained crystals of the monohydrate by cooling the hot aq. soln.; and C. A. Wurtz, by adding alcohol to the aq. soln. The crystals are white or colourless needles or prisms with a pearly lustre. They belong to the monoclinic system, and, according to C. F. Rammelsberg, have the axial ratios $a:b:c=1·575:1:1·200$, and $\beta=79°\ 40'$. H. Töpsöe gave 2·0017 : 1 : 1·5760, and $\beta=99°\ 33'$. Twinning about the (101)-face frequently occurs. According to H. G. F. Schröder, the sp. gr. is 2·839–2·911; and, according to F. W. Clarke, 2·8718 at 10°; 2·8971 at 17°; 2·780 at 21·6°; and 2·775 at 23·3°. P. Walden gave for the eq. electrical conductivity, λ, for soln. with a gram-equivalent in v litres:

v .	32	64	128	256	512	1024	∞
λ .	78·7	84·1	88·2	91·8	94·6	97·3	105·3

G. Bredig made observations on this subject. The dry salt, said C. A. Wurtz, is stable in air; and no loss in weight over conc. sulphuric acid was observed by C. F. Rammelsberg. C. A. Wurtz said the salt becomes anhydrous at 100°; and C. F. Rammelsberg, at 100°–150°. H. Rose said that when the salt is heated, water is first evolved, and then spontaneously inflammable phosphine. The residue has a reddish colour, presumably owing to the formation of a little red phosphorus,

C. F. Rammelsberg represented the reaction: $13Ba(H_2PO_2)_2=6Ba_2P_2O_7+Ba(PO_3)_2+12PH_3+4H_2+4H_2O$. J. Thomsen gave 0·29 Cal. for the heat of soln. of a mol of the monohydrate in 800 mols of water; and for the heat of neutralization of the acid with $Ba(OH)_2$aq., 30·92 Cals. C. A. Wurtz said that 100 parts of water at ordinary temp. dissolve 28·5 parts of salt; and 100 parts of boiling water, 33·3 parts of salt; it is insoluble in alcohol; and when heated with potash-lye, barium phosphite is precipitated—the reaction is symbolized: $Ba(H_2PO_2)_2+2KOH=BaHPO_3+K_2HPO_3+2H_2$. By heating the crystals of the salt with nitric acid, C. F. Rammelsberg obtained barium metaphosphate.

H. Rose evaporated in vacuo a soln. of beryllium hydroxide in phosphoric acid, and obtained a sticky substance, presumably **beryllium hypophosphite,** $Be(H_2PO_2)_2$, which dried to a hard mass with a conchoidal fracture. B. Bleyer and B. Müller mixed a mol. of beryllium sulphate and barium hypophosphite in aq. soln.; evaporated the filtrate over conc. sulphuric acid and obtained a glassy residue with the composition just indicated. H. Rose obtained **magnesium hypophosphite,** $Mg(H_2PO_2)_2.6H_2O$, by boiling the calcium salt with magnesium oxalate and water; and C. A. Wurtz, by the double decomposition of the barium salt and magnesium sulphate. H. Rose, and C. F. Rammelsberg wrongly described the crystals as octahedrons with the faces of a cube. J. Beckenkamp showed that the crystals are tetragonal bipyramids, with the axial ratio $a:c=1:0·9878$. The birefringence is feeble and positive. F. W. Clarke gave for the sp. gr. 1·5886 at 12·5°, and 1·5681 at 14·5°. H. Rose found that the crystals effloresce in air, and when heated to 100°, C. A. Wurtz found that they lost five-sixths of their water of crystallization, and the remainder at 180°. When heated to a higher temp., H. Rose found that phosphine is emitted, and a reddish mass remains. C. F. Rammelsberg represented the reaction: $5Mg(H_2PO_2)_2=2Mg_2P_2O_7+Mg(PO_3)_2+4PH_3+4H_2$. When the crystals are heated with nitric acid, H. Rose found that magnesium metaphosphate is formed. By dissolving zinc carbonate in hypophosphorous acid, and evaporating the soln. in vacuo, H. Rose obtained indistinct crystals. The salt is obtained by double decomposition in aq. soln.; and C. A. Wurtz found that if evaporated at ordinary temp., crystals of hexahydrated **zinc hypophosphite,** $Zn(H_2PO_2)_2.6H_2O$, isomorphous with the magnesium salt are formed; and by evaporating the hot soln., the rhombohedral crystals, dried at 100°, are monohydrated. F. W. Clarke gave 2·016 for the sp. gr. of the hexahydrate at 12·5°; and 2·014 at 19·5°. H. Rose and C. F. Rammelsberg found that the salt is decomposed by heat as in the case of the magnesium salt. H. Rose obtained **cadmium hypophosphite,** by evaporating in vacuo a soln. of hypophosphorous acid sat. with cadmium carbonate. The cadmium salt behaves like the zinc salt when heated. H. Rose obtained indications of the existence of a complex salt *calcium cadmium hypophosphite* by evaporating the filtrate from the liquor obtained by boiling cadmium oxalate, calcium hypophosphite, and water. The **mercury hypophosphites** have not been prepared. H. Rose found that mercuric chloride is reduced to mercurous chloride and to mercury when treated with hypophosphorous acid. S. Hada observed that **mercurous nitratohypophosphite,** $Hg(H_2PO_2).Hg(NO_3).H_2O$, is precipitated on adding a soln. of potassium or barium hypophosphite to a soln. of mercuric or mercurous nitrate, free from nitrous acid, but the mercury soln. must not be too dil., and as free from acid as possible; care must also be taken to avoid using excess of the hypophosphite. The compound is not obtained when the mercury nitrate soln. is added to the hypophosphite, or if too much of the latter is added to the mercury nitrate, as in either case the double salt is at once decomposed. Since the formation of the salt from mercuric nitrate necessarily involves the oxidation and waste of much of the hypophosphite, and also yields a mother-liquor which acts strongly on the precipitate, mercurous nitrate should be used; moreover, potassium hypophosphite is preferable to the barium salt, as with the latter the precipitate is liable to contain barium apparently as nitrate. As the white precipitate obtained on adding potassium hypophosphite to an excess of mercurous nitrate is slowly decomposed when left in contact with the mother-liquor, it must be quickly collected and drained on a tile, without previous washing. The *mercurous nitratohypophosphite* thus obtained is unstable when moist, although when dry it decomposes but slowly, becoming grey in the course of time. It is a white, micaceous powder, slightly soluble in water, by which it is soon decomposed with separation of mercury; it loses its water of crystallization in a vacuum desiccator, but undergoes scarcely any decomposition, even when kept for some time. When heated, it turns grey above 90°, and explodes a little above 100°, yielding mercury and nitrous vapours; it also explodes if touched with a hot wire. With hydrochloric acid, it first gives mercurous chloride and then metallic mercury, whilst hot, strong nitric acid dissolves it completely with the evolution of nitrous fumes. Sodium chloride converts it into mercurous chloride and sodium hypophosphite, which only very slowly react, yielding metallic mercury. Potassium hydroxide blackens it, probably from formation of mercurous oxide.

H. Rose reported **aluminium hypophosphite** to be formed by dissolving aluminium hydroxide in cold hypophosphorous acid, and evaporating the filtered soln. in vacuo. The viscid product dries to a hard mass with a conchoidal fracture, and is not deliquescent. When heated in a retort, phosphine is evolved and a reddish substance remains. C. F. Rammelsberg prepared **thallous hypophosphite,** TlH_2PO_2, by the double decomposition of the barium salt with thallous sulphate. The prismatic crystals are anhydrous, and belong to the rhombic system with the axial ratios $a : b : c = 0{\cdot}786 : 1 : 0{\cdot}805$. They melt at 150° and are decomposed by heat: $5TlH_2PO_2 = Tl_4P_2O_7 + TlPO_3 + 2PH_3 + 2H_2$. According to O. Hauser and H. Herzfeld, **zirconium hypophosphite,** $Zr(H_2PO_2)_4.H_2O$, is obtained by adding hypophosphorous acid to a soln. of zirconium nitrate until the precipitate has completely redissolved, and then adding alcohol. It forms colourless, highly refracting crystals, which become deep violet very rapidly in direct sunlight, or in the course of several weeks in diffused daylight, without any other perceptible change. C. F. Rammelsberg prepared **cerium hypophosphite,** $Ce(H_2PO_2)_3.H_2O$, in thin prismatic crystals, from the soln. obtained by decomposing the barium salt with cerium sulphate. The salt decomposes when heated yielding products like those with the calcium and strontium salts. O. Kauffmann reported **thorium hypophosphite,** $Th(H_2PO_2)_4.H_2O$, to be found by mixing a cold soln. of the sodium salt with one of thorium nitrate. The salt is washed free from nitric acid, and dried on a porous tile; the anhydrous salt was obtained by adding thorium nitrate to a soln. of hypophosphorous acid. The salt is insoluble in water, but very soluble in conc. mineral acids. When the soln. in conc. hydrochloric acid is evaporated over a flame, aggregates of crystals of **thorium hydroxytrihypophosphite,** $Th(OH)(H_2PO_2)_3.4H_2O$, are formed. The crystals are insoluble in water, but soluble in dil. hydrochloric acid.

The *tin hypophosphites* have not been prepared; A. Terni and C. Padovani found that when solid or a conc. soln. of stannous chloride is added to a conc. soln. of sodium hypophosphite, there is a voluminous white precipitate of **stannic chlorohypophosphite,** $SnCl_4.Sn(H_2PO_2)_4.3H_2O$, which is strongly reducing. This compound is dehydrated at 140°, and, at 190°, it decomposes, with a characteristic reddening and evolution of phosphine. If the heating is stopped immediately, and the mass extracted with conc. hydrochloric acid, the composition of the bright red residue approximates to P_4O. T. von Grotthus, H. Rose, and C. A. Wurtz made observations on **lead hypophosphite,** $Pb(H_2PO_2)_2$. H. Rose obtained it by saturating a hot aq. soln. of hypophosphorous acid with lead oxide. If the soln. is heated, lead is precipitated. C. A. Wurtz treated the acid with freshly precipitated lead carbonate. In both cases, the filtered soln. was evaporated. E. von Herz treated a hot sat. soln. of the calcium salt with a hot sat. soln. of lead nitrate, when crystals of lead hypophosphite separated on cooling. According to H. Rose, and C. A. Wurtz, the small rhombic prisms have a feeble acidic reaction towards litmus, and they lose no water at 100°. When heated in a retort, phosphine is evolved; and C. F. Rammelsberg represented the reaction: $9Pb(H_2PO_2)_2 = 4Pb_2P_2O_7 + Pb(PO_3)_2 + 8PH_3 + 4H_2 + 2H_2O$. W. Ipatieff and co-workers found that lead hypophosphite gives phosphorous acid, lead oxide, and black phosphorus when it is heated in a current of hydrogen. H. Rose found the salt to be sparingly soluble in cold water, but more readily soluble in hot water; it is not soluble in alcohol, and alcohol precipitates the salt from its aq. soln. in pearly scales. The aq. soln. is not decomposed by boiling. Aq. ammonia in excess precipitates what might be an impure basic salt. H. Rose believed that an excess of lead oxide formed a basic salt; C. A. Wurtz, lead phosphite. E. von Herz prepared highly explosive **lead nitratohypophosphite,** $Pb(NO_3)_2.Pb(H_2PO_2)_2$, or $Pb(NO_3)(H_2PO_2)$, by adding a hot saturated soln. of lead nitrate (331 grms.) to a boiling saturated soln. of calcium hypophosphite (170 grms.), and cooling the mixture rapidly with efficient stirring, when white, crystalline lead hypophosphite separates. Two hundred and fifty grms. of the latter are added with stirring to a boiling soln. of lead nitrate (500 grms.) in water (1·5 litres), and rapidly cooled. Its rate of detonation is greater than that of mercury fulminate and approximately equal to that of lead azide. Its small energy content, or the relatively small volume of gas liberated by its decomposition (117 litres per kilo., as contrasted with 230 litres with lead azide and 314 litres with mercury fulminate), inhibits its use as initial explosive in the usual amount of charge. Its suitable sensitiveness and detonation point, its great stability, and the high temperature of its flame render it very appropriate for percussion-fuse compositions. The double compound, dried at 40°–50°, is practically useful only when it is obtained as a heavy, granular, crystalline powder; it is less suitable in the form of needles or as a felted, voluminous mass.

S. Hada prepared **bismuth hypophosphite,** $Bi(H_2PO_2)_3.H_2O$, by mixing a soln. of bismuth nitrate, free from any unnecessary excess of nitric acid, with barium or potassium hypophosphite, avoiding excess of bismuth nitrate, as the salt is soluble in it. The bismuth hypophosphite, which is precipitated as a white crystalline powder, slowly decomposes in contact with the mother-liquor, but, if collected at once and dried on a porous tile, it can be preserved for days unchanged. L. Vanino and F. Hartl obtained it by adding hypophosphorous acid or its sodium salt to an aq. soln. of bismuth nitrate and mannitol. The white, crystalline precipitate decomposed slowly when dry; but more quickly when moist, giving bismuth. S. Hada found that bismuth hypophosphite decomposes very readily when heated, becoming black and giving off phosphine at temperatures only a little above 100°. At a stronger heat, metallic globules of bismuth and bismuth phosphate are obtained: $3Bi(H_2PO_2)_3 = 2Bi + Bi(PO_3)_3 + 6P + 9H_2O$. This hypophosphite is noticeable for yielding metal instead of phosphide.

C. A. Wurtz reported **chromium hydroxydihypophosphite,** $2Cr(OH)(H_2PO_2)_2.3H_2O$, to be formed by mixing soln. of the barium salt and chromic sulphate, and evaporating the green filtrate. The dark green, amorphous product decomposes at 200°, and is then no longer soluble in water or dil. acids. According to F. Mawrow and J. Zoneff, **chromium hypophosphite,** $Cr(H_2PO_2)_3.2H_2O$, is formed when a soln. of freshly precipitated chromium hydroxide in hypophosphorous acid yields a green mass on evaporation on the water-bath, which may be washed with water and dried over sulphuric acid. Soln. of potassium hypophosphite and chromium alum give first a deposit of potassium sulphate, and the soln. yields on further evaporation a gummy mass, from which it has not been possible to obtain a definite salt. For the action of hypophosphorous acid on molybdenum salts, *vide supra.* According to F. Mawrow, when hypophosphorous acid is added to a soln. of ammonium molybdate in conc. hydrochloric acid, a bluish-green soln. is produced and a violet deposit of **molybdenum oxyhypophosphite,** $Mo_5O_8(H_3PO_2)_7,3H_2O$, with a coppery lustre obtained. This deposit is soluble in cold water, giving a green soln. which, on exposure to air, becomes blue. It is decomposed by alkali-lye, forming a green precipitate. It is soluble in conc. sulphuric acid with a blue colour, and on dilution a yellowish-brown precipitate is formed. Heated on platinum foil, it explodes and leaves a grey residue. On heating an aqueous soln. of this, it becomes blue, and on evaporating at 90°–95°, a blue residue is obtained which is soluble in water or alcohol with a blue colour and explodes when heated. Its composition is represented by $Mo_5O_{13}(H_3PO_2)_8,H_2O$. Both these compounds are strong reducing agents, indicating that the phosphorus is present in the condition of hypophosphorous acid. It is doubtful if the formulæ given are correct, but it is certain that the substances are not compounds of molybdic acid, but of a lower oxide of molybdenum. The blue soln. gives characteristic precipitates with salts of ammonium, lead, and bismuth. F. Mawrow and N. Nikoloff said that the blue compound obtained by boiling the violet compound has the composition **molybdosic hypophosphite,** $Mo_5O_{14}.6H_3PO_2.4H_2O$, or $Mo_2O_5.3MoO_3.6H_3PO_2.4H_2O$. Its soln. gives a blue precipitate of **ammonium hypophosphitomolybditomolybdate,** $(NH_4)_2O.Mo_2O_5.5MoO_3.2H_3PO_2.4H_2O$, when treated with ammonium chloride; the precipitate with a sodium salt is **sodium hypophosphitomolybditomolybdate,** $Na_2O.Mo_2O_5.5MoO_3.3H_3PO_2.4H_2O$; with cobaltous chloride, **cobaltous hypophosphitomolybditomolybdate,** $CoO.Mo_2O_5.5MoO_3.2H_3PO_2.7H_2O$; and with lead nitrate, the **lead hypophosphitomolybditomolybdate** is mixed with lead hypophosphite. Only **barium hypophosphitomolybdate,** $BaO.Mo_7O_{20}(H_3PO_2,)_3.12H_2O$, has been examined. O. W. Gibbs reported **ammonium hypophosphitomolybdate,** $2(NH_4)_2O.8MoO_3.2H_3PO_2.2H_2O$, to be formed on mixing $(NH_4)_6Mo_7O_{24}$ with hypophosphorous acid, and then hydrochloric acid. The crystalline salt was washed with cold water. The colourless prismatic crystals are easily soluble in hot water. W. Weinberg obtained the ammonium hypophosphitomolybdate, $(NH_4)_2H.PO_2.4MoO_3.3{\cdot}5H_2O$, by mixing sodium hypophosphite and ammonium molybdate in as little water as possible, and adding hydrochloric acid. He also obtained **sodium hypophosphitomolybdate,** and **potassium hypophosphitomolybdate,** as well as the guanidinium salt. O. W. Gibbs reported **potassium hypophosphitotungstate,** $4K_2O.18WO_3.6H_3PO_2.7H_2O$, to be formed by the action of a conc. soln. of hypophosphorous acid on sodium paratungstate, dissolving the yellow product in water, and treating it with a soln. of potassium bromide. The colourless crystals are decomposed by heat. The salt is soluble in hot water, but the soln. becomes turbid, and effervesces when an alkali carbonate is added; with silver nitrate, a white precipitate of **silver hypophosphitotungstate** is formed which blackens when the soln. is hot; barium chloride gives a white precipitate of **barium hypophosphitotungstate**; and mercurous nitrate a white precipitate of **mercurous hypophosphitotungstate,** which becomes dirty yellow when the liquid is warmed.

According to V. Kohlschütter and H. Rossi, *uranium hypophosphite* has not been investigated, but M. Lobanoff prepared **uranium hypophosphite,** $U(H_2PO_2)_4$, and **uranium hydrohypophosphite,** $U(H_2PO_2)_4.H_3PO_2$, by adding the correct proportions of the acid to acidic soln. of uranic sulphate. According to A. Rosenheim and G. Trewendt, **uranyl hypophosphite,** $UO_2(H_2PO_2)_2$, is obtained in microcrystalline, yellow prisms, by agitating soln. of a mol of uranyl nitrate and 4 mols of sodium hypophosphite. The salt is almost insoluble in water, but readily soluble in excess of a soln. of either uranyl nitrate or sodium hypophosphite. They also prepared a yellow *trihydrate;* and C. F. Rammelsberg prepared the *monohydrate,* $(UO_2)(H_2PO_2)_2.H_2O$. Freshly precipitated ammonium uranate is transformed in an aq. soln. of hypophosphorous acid into the crystalline salt, which is very sparingly soluble in water. The water of crystallization is lost between 100° and 200°; and at a higher temp., it decomposes with the evolution of hydrogen and a detonation. Traces of phosphorus and phosphine are formed, and a grey residue with the composition: UP_2O_6, which is considered to be a mixture of pyrophosphate, metaphosphate, and phosphide. The main reaction is symbolized: $(UO_2)(H_2PO_2)_2{=}U(PO_3)_2{+}2H_2$. When the uranyl hypophosphite is evaporated with nitric acid, C. F. Rammelsberg found that **uranyl metaphosphate**, $(UO_2)(PO_3)_2$, is produced. A. Rosenheim and G. Trewendt observed that if uranyl hypophosphite be treated with a soln. of 4 mols of sodium hypophosphite, it forms slender, pale yellow needles of **sodium diuranyl pentahypophosphite**, $Na[(UO_2)_2(H_2PO_2)_5].4\frac{1}{2}H_2O$, or the *hexahydrate;* the corresponding **potassium diuranyl pentahypophosphite** forms yellow crusts; **ammonium diuranyl pentahypophosphite**, pale yellow leaflets; and the *guanidinium* salt, aggregates of needles. If uranyl hypophosphite be treated with 6 to 8 mols of sodium hypophosphite, it forms **sodium uranyl dihypophosphite**, $Na[(UO_2)(H_2PO_2)_2].3{\cdot}5H_2O$, in large, rectangular plates; the *pentahydrate* was also prepared. Attempts to prepare corresponding compounds with other alkali hypophosphites yielded salts of the series $R[(UO_2)_2(H_2PO_2)_5]$. The compounds form uranyl hypophosphite, and ten or more molecular proportions of alkali hypophosphite could not be caused to crystallize.

H. Rose obtained **manganese hypophosphite**, $Mn(H_2PO_2)_2.H_2O$, by boiling the calcium salt with manganese oxalate; and C. A. Wurtz, and C. F. Rammelsberg, by the double decomposition of barium hypophosphite and manganese sulphate. The small, rose-red crystals are believed by C. F. Rammelsberg to be monoclinic prisms. They lose no water at 100°, but become anhydrous at 150°, according to C. A. Wurtz, and at 180°–200°, according to C. F. Rammelsberg, and when heated to a higher temp. phosphine is evolved and some red phosphorus is formed: $5Mn(H_2PO_2)_2=2Mn_2P_2O_7+Mn(PO_3)_2+4PH_3+4H_2$. H. Rose prepared **ferrous hypophosphite**, $Fe(H_2PO_2)_2.6H_2O$, in small green crystals—said to be octahedral, but see the magnesium salt—by dissolving iron in hypophosphorous acid out of contact with air; and C. A. Wurtz, by the double decomposition of the barium salt with ferrous sulphate. The aq. soln. on evaporation furnishes crystals of the salt. It is readily oxidized by exposure to air. H. Rose said that hydrated ferric oxide can be dissolved in the cold acid without reduction, forming a white **ferric hypophosphite** which is sparingly soluble in the free acid, and yields spontaneously inflammable phosphine when heated. When hydrated ferric oxide is boiled with hypophosphorous acid, a soln. of ferrous hypophosphite is obtained, and ferric phosphate is precipitated. The stability of ferric hypophosphite is remarkable in that tervalent iron is associated with a strongly reducing acid. W. Hieber represented the constitution of the normal salt, $Fe(H_2PO_2)_3$ by $[Fe_3(H_2PO_2)_6](H_2PO_2)_6$, where $[Fe_3(H_2PO_2)_6]$ is considered to be a basic, tervalent radicle. He obtained this salt by slowly adding a hot soln. of ferric chloride to a hot soln. of sodium hypophosphite, so that the precipitate first formed is dissolved. It can also be made by treating ferric hydroxide freshly precipitated in the cold, with hypophosphorous acid. The normal salt is also obtained by digesting the basic ferric hypophosphites with the acid. By working with less conc. soln., a series of **ferric hydroxyhypophosphites** was prepared. Thus, *triferric hydroxyhexaphosphitodihypophosphite*, $[Fe_3(OH)(H_2PO_2)_6](H_2PO_2)_2+24H_2O$, was obtained; likewise the complex $[Fe_3(OH)(H_2PO_2)_6](H_2PO_2)[Fe_3(H_2PO_2)_6(OH)_2]H_2PO_2+nH_2O$; as well as *triferric dihydroxyhexahypophosphitohypophosphite*, $[Fe_3(H_2PO_2)_6(OH)_2]H_2PO_2+nH_2O$; and *triferric trihydroxypentahypophosphitohypophosphite*, $[Fe_3(H_2PO_2)_5(OH)_3]H_2PO_2+nH_2O$. If triferric hydroxyhexahypophosphitodihypophosphite be warmed with a soln. of potassium hypophosphite, there is formed **potassium aquopentahypophosphitoferrate**, $K_2[Fe(H_2O)(H_2PO_2)_5]$, and similarly for **sodium aquopentahypophosphitoferrate**, $Na[Fe(H_2O)(H_2PO_2)_5]$. Another series of complex ferric hydroxy- or aquohypophosphites has been prepared:

$[Fe_3(HO)(H_2PO_2)_6](H_2PO_2)_2.nH_2O$;
$[Fe_3(HO)(H_2PO_2)_6]_2[Fe(H_2O)(H_2PO_2)_5](H_2PO_2)_2$;
$[Fe_3(H_2PO_2)_6][Fe(H_2O)(H_2PO_2)_5][Fe_3(HO)(H_2PO_2)_6](H_2PO_2)_3$;
$[Fe_3(HO)(H_2PO_2)_6][Fe(H_2O)(H_2PO_2)_5$;
$[Fe_3(H_2PO_2)_6][Fe(H_2O)(H_2PO_2)_5$;
$[Fe_3(H_2PO_2)_6][F_3(HO)(H_2PO_2)_6[Fe(HO)(H_2PO_2)_5(H_2PO_2)_2$;
$[Fe_3(H_2PO_2)_6]_2[Fe(HO)(H_2PO_2)_5](H_2PO_2)_3$;
$[Fe_3(H_2PO_2)_6][Fe(H_2O)(H_2PO_2)_5](H_2PO_2)$.

W. Hieber prepared a number of complex **ferric sulphatohypophosphites,** $[Fe_3(H_2PO_2)_6]SO_4(H_2PO_2).4H_2O$; $[Fe_3(H_2PO_2)_6]\frac{1}{2}SO_4(H_2PO_2)_2.4H_2O$; $[Fe_3(H_2PO_2)_6](HSO_4)_3.nH_2O$; $[Fe_3(H_2PO_2)_6]_2(HSO_4)_2(H_2PO_2)_2SO_4.24H_2O$; $[Fe_3(H_2PO_2)_6]_2\frac{1}{2}SO_4(HSO_4)_4(H_2PO_2).30H_2O$; $[Fe_3(H_2PO_2)_6][Fe_3(H_2PO_2)_6(OH)](SO_4)_2(H_2PO_2).24H_2O$; $[Fe_3(H_2PO_2)_6(OH)].nH_2O$. The **ferric perchloratohypophosphites :** $[Fe_3(H_2PO_2)_6](ClO_4)_2H_2PO_2.\frac{1}{2}H_3PO_2.18H_2O$; and $[Fe_3(H_2PO_2)_6](ClO_4)(H_2PO_2)_2.nH_2O$. The **ferric chlorostibnohypophosphite :** $[Fe_3(H_2PO_2)_6]_2(SbCl_6)_3(H_2PO_2)_3.18H_2O$. The **ferric chlorohypophosphites :** $[Fe_3(H_2PO_2)_6][FeCl_4](H_2PO_2)_2.2H_3PO_2.10H_2O$; $[Fe_3(H_2PO_2)_6][FeCl_3(H_2PO_2)]_2H_2PO_2.12H_2O$; $[Fe_3(H_2PO_2)_6][FeCl_3.(H_2PO_2)][FeCl_4)H_2PO_2.6H_2O$; and $[Fe_3(HO)(H_2PO_2)_6]_2Cl_2(H_2PO_2).15H_2O$. The **ferric bromohypophosphite :** $[Fe_3(H_2PO_2)_6][FeBr_4](H_2PO_2)_2.12H_2O$. The **ferric nitratohypophosphite :** $[Fe_3(H_2PO_2)_6][Fe_3(HO)(H_2PO_2)_6](H_2PO_2)_3(NO_3)_2).24H_2O$.

H. Rose dissolved freshly precipitated cobalt hydroxide in cold hypophosphorous acid, and evaporated the filtered soln. in vacuo, whereby red crystals of **cobalt hypophosphite,** $Co(H_2PO_2)_2.6H_2O$, isomorphous with the magnesium salt are formed. S. Stevanovic, and J. Beckenkamp showed that the crystals are tetragonal bipyramids with the axial ratio, according to the former, $a : c = 1 : 0{\cdot}9892$. Twinning occurred about the (101)-face ; the corrosion figures were found to be approximately equiangular and three-sided. The birefringence is feeble and positive. F. W. Clarke gave 1·808–1·811 for the sp. gr. of the salt at 18·5°. C. A. Wurtz found that the water of crystallization is lost at 100° ; and C. F. Rammelsberg, at 120°–130° ; the salt begins to decompose at 150° ; and it becomes black : $3Co(H_2PO_2)_2 = 2Co(PO_3)_2 + CoP + PH_3 + 9H$. When evaporated with nitric acid, H. Rose found that the hypophosphite is converted into the metaphosphate. H. Rose, and C. A. Wurtz prepared **nickel hypophosphite,** $Ni(H_2PO_2)_2.6H_2O$, by the methods employed for the cobalt salt. The green crystals, said H. Rose, appear to be cubes ; and C. A. Wurtz, and C. F. Rammelsberg, octahedra isomorphous with the cobalt salt. F. W. Clarke gave 1·856 for the sp. gr. of the salt at 18° ; 1·844 at 19° ; and 1·824 at 19·8°. C. A. Wurtz found the salt is dehydrated at 100° ; and C. F. Rammelsberg said the decomposition begins at 100°, and he represented the reaction by $3Ni(H_2PO_2)_2 = 2Ni(PO_3)_2 + NiP + PH_3 + 9H$. The salt is soluble in water ; and when the soln. is evaporated at 100°, some nickel is reduced. The moist crystals are also reduced if heated quickly to 120°. The stability of the *nickel amminohypophosphite* was discussed by F. Ephraim and co-workers.

R. Engel prepared **platinous hypophosphite,** $Pt(H_2PO_2)_2$, by passing phosphine at 0° into a soln. of platinic chloride in 90 per cent. alcohol acidified with a drop of hydrochloric acid ; it is washed with alcohol and then with boiling water ; dried in the cold, and then at 130°. The yellow salt is not altered at 130°, but it decomposes at a higher temp. into spontaneously inflammable phosphine. It is insoluble in water, alcohol, and in hydrochloric, sulphuric, and acetic acids ; it is soluble with oxidation in nitric acid, and chlorine-water. Boiling conc. potash-lye decomposes it with the evolution of hydrogen and the deposition of platinum. Placed in suspension in soln. of gold, silver, copper, mercury, or palladium, it immediately reduces these salts in the cold, and is itself partially reduced.

§ 16. Phosphorus Trioxide, or Phosphorous Oxide

In 1777, B. G. le Sage[1] passed a very slow current of well-dried air through a tube containing fragments of phosphorus at a low temp., and obtained a white, flocculent powder of what must have been *phosphorous anhydride*, **phosphorous oxide**, or **phosphorus trioxide**, P_2O_3, or rather P_4O_6. This substance was at first confused with *les fleurs de phosphore* obtained by the combustion of phosphorus in air. A. L. Lavoisier recognized the difference dependent on the conditions under which the phosphorus is burnt, and he inferred the existence of two oxides of phosphorus—one, made by B. G. le Sage, *spontanément à l'air par la destruction lente du phosphore*, and the other obtained *par combustion*. P. A. Steinacher,[2] and H. Davy, also recognized that phosphorous oxide and some phosphoric oxide are produced by the slow oxidation of phosphorus; but the relationship between the two oxides was not made clear until P. L. Dulong's memoir: *Sur les combinaisons du phosphore avec oxygène* in 1816, when it was shown that the two oxides are related to phosphorus much as the two oxides of carbon are related to carbon. The slow oxidation of phosphorus has been previously discussed—*vide supra.*

Phosphorous oxide is produced by the imperfect combustion of phosphorus, such as occurs when that element is warmed in contact with a limited supply of air, slowly renewed, or much rarefied. P. A. Steinacher heated phosphorus to 100° in a narrow glass tube containing air, and found that phosphorous oxide, accompanied by a small proportion of phosphoric oxide, sublimes. J. J. Berzelius burnt the phosphorus in a glass tube through which only a very slow current of air was passed; and H. Davy heated the phosphorus in highly rarefied air. J. M. Cabell sublimed the product at about 177° in an atm. of hydrogen. According to E. Jungfleisch, the oxidation of pure dry phosphorus at low temp. in pure oxygen at atm. press. gives exclusively phosphoric oxide, but at press. of 18–20 mm. the immediate products of oxidation are phosphorous oxide and a bright yellow oxide—the tetritoxide. When oxidized in oxygen at low press., the phosphorus becomes very luminous, partially fuses, and soon ignites with a large pale glaucous flame which is extinguished in a few moments, all the oxygen being absorbed. After cooling, the unchanged phosphorus is left surrounded by phosphoric oxide (formed before the reduction in press.), by the yellow compound (a little farther away), and lastly by a white aureole of phosphorous oxide. On admission of a very small quantity of air, the vapour of the latter burns with a phosphorescent glow, whilst a larger quantity of air causes the ignition first of the solid P_2O_3, and then of the remaining phosphorus. Introduction of water instead of air into the combustion vessel produces bright flashes of light, as the dissolved oxygen oxidizes small quantities of P_2O_3 vapour. The resulting soln. contains phosphoric and phosphorous acids with the yellow compound in suspension, the phosphorous acid amounting to 57·9 per cent. of the total phosphorus. The oxidation in this manner can be effected continuously in a tube, and the P_2O_3 obtained in well-defined crystals. Whether air, pure oxygen, or oxygen mixed with an inert gas is used at low press. the products of oxidation are the same. Partial oxidation of phosphorus in this manner renders it spontaneously inflammable, owing to the inflammability of the phosphorous oxide formed. According to R. Cowper and V. B. Lewes, when dry air is passed over molten phosphorus, the product contains 70·1 to 78·2 per cent. of phosphoric oxide, 3·2 to 9·6 per cent. of phosphorous oxide, and 17·0 to 26·6 per cent. of yellow phosphorus which changes into red phosphorus on exposure to light as noted by A. Irving, who overlooked the presence of yellow phosphorus. A. Sommer described some methods of burning phosphorus in a limited supply of air. T. E. Thorpe and A. E. H. Tutton employed the following mode of preparing phosphorous oxide by this process:

The phosphorus is placed in a glass tube, *A*, which is bent as shown in Fig. 31, and fitted into one end of a long tube cooled by a jacket, *B*, containing water at 60°. The cooled tube is fitted to a U-tube, *C*, immersed in a freezing-mixture; a plug of glass-wool is placed in the condenser tube near the U-tube. The phosphorus is ignited, and a slow stream of air is drawn through the apparatus by means of an aspirator connected to the U-tube. The phosphorus pentoxide is arrested by the glass-wool, and phosphorus oxide passes into the U-tube, where it is condensed into a white crystalline mass. The wash-bottle, *E*, with conc. sulphuric acid protects the product from moisture. At the end of the experiment, the solid in the U-tube can be melted and run into the bottle *D*.

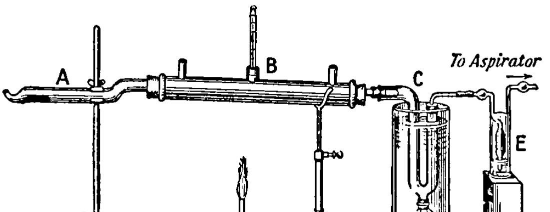

FIG. 31.—The Preparation of Phosphorus Trioxide.

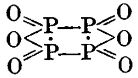
A. Naquet said that phosphorous oxide is formed by the action of phosphorus trichloride on phosphorous acid: $H_3PO_3+PCl_3=3HCl+P_2O_3$. The reaction was studied by A. Gautier, A. Besson, and K. Kraut. A. Béchamp obtained this oxide by the action of phosphorus trichloride on acetic anhydride: $3(CH_3CO)_2O+2PCl_3=6CH_3COCl+P_2O_3$; and T. E. Thorpe, and C. H. Bothamley and G. R. Thompson found that the reaction with acetic acid is analogous: $3CH_3COOH+2PCl_3=3CH_3COCl+3HCl+P_2O_3$—propionic and butyric acids give similar results. There are a number of side reactions, and some phosphorus tetritoxide is formed (*q.v.*).

P. A. Steinacher reported that phosphorous oxide forms white bulky flakes which smell like garlic; the oxide possesses a sour sharp taste; and reddens moist litmus, but not that which is dry. J. M. Cabell showed that the sublimed oxide consists of monoclinic **crystals.** T. E. Thorpe and A. E. H. Tutton reported that the sublimed oxide in the cooler part of the condensing tube consists of minute crystals aggregated into a snow-white mass; in the warmer parts, radiating aggregates of crystals are formed; and when the melted oxide is cooled, or when the soln. of the oxide in benzene or carbon is evaporated, well-defined crystals are obtained. Exact measurements of the crystals are not possible because of the oxidation and deliquescence of the oxide on exposure. The crystals are in all cases monoclinic, and there is no evidence of dimorphism such as occurs with arsenious and antimonious oxides. The crystals show the pinacoidal faces, *a*(100) and *b*(010), several prism faces, a pair of complementary pyramidal forms. The extinctions upon *a* are parallel to the prism edges, whilst those on *b* make an angle of about 20° with the prism edges. In convergent light an optic axis with its system of rings is seen on looking through the orthopinacoid *a* towards the edge of the field in the direction indicated in one of the crystals shown in Fig. 4. When the crossed Nicols are parallel to the axial edges, the brush passes across the centre of the field in a line parallel to the vertical axis. The optic axial plane, therefore, appears to be the symmetry plane *b*. As phosphorous oxide is also in all probability monoclinic, with an extinction upon the symmetry plane of about 20°, it would appear that there is a regular relationship between phosphorous, arsenious, and antimonious oxides, such that there is a gradual approach to the higher symmetry of the rhombic system which is ultimately attained by antimonious oxide. The optic axial plane is also identical with the symmetry plane in phosphorous and arsenious oxides, and also for all the colours of the spectrum, with the exception of red, for which colour the plane crosses to one at right angles, as in the case of antimonious oxide.

The **vapour density** found by T. E. Thorpe and A. E. H. Tutton is 7·67 to 7·83 at temp. ranging from 131° to 184°. The theoretical value for P_2O_3 is 3·81, and that for P_4O_6 is 7·62. Hence, the formula P_4O_6. This is in agreement with the effect of this oxide on the f.p. of benzene; and, according to R. Schenck and co-workers, on the f.p. of naphthalene. G. le Bas' observations on the mol. vol. are in agreement with the formula:



T. E. Thorpe and A. E. H. Tutton found the **specific gravity** of the liquid oxide to be 1·9431 at 21°/4°, and there is a 9·0 per cent. contraction on solidification so that the sp. gr. of the solid oxide is 2·135 at 21°/4°. The sp. gr. of the oxide at its b.p., 173·1°, is 1·6897, and the **specific volume,** 130·2. Accepting H. Kopp's and H. Buff's value 7·8 for the sp. vol. of oxygen joining to different atoms by single linkages, the sp. vol. of free phosphorus is 20·9, and the calculated sp. vol. of phosphorus in combination as phosphorous oxide has the same value. This is taken to mean that the phosphorus in both cases is quinquevalent. According to T. E. Thorpe and A. E. H. Tutton, the relative vol., *v*, of the molten oxide is:

	27·10°	36·07°	63·20°	89·48°	117·68°	140·30°
Vol. . . .	1·0000	1·0078	1·0316	1·0557	1·0827	1·1058

these results, corrected for the thermal expansion of glass, can be represented by $v=1+0{\cdot}0_3 91377\theta-0{\cdot}0_6 11175\theta^2+0{\cdot}0_8 38607\theta^3$, when θ° ranges betwccn 27·10° and 140·30°. The **thermal expansion** of the liquid follows directly from:

	25°	30°	50°	75°	100°	125°	150°	170°	173 1°
Vol. . .	1·000	1·0046	1·0228	1·0459	1·0695	1·0941	1·1200	1·1419	1·1454

Phosphorous oxide has the **melting point** 22·5°, when it forms a clear, colourless liquid which freezes at 21°, and has a marked tendency to undercooling. R. Schenck and co-workers gave for the **vapour pressure,** p mm. of the liquid:

	22·4°	30·8°	40·8°	50·0°	64·4°	72·7°	91·2°
p . .	2·7	4·1	6·0	9·5	18·4	50·8	297·9

T. E. Thorpe and A. E. H. Tutton showed that the **boiling point** is 173·1° at 760 mm. There is no decomposition at this temp. in an atm. of an inert gas—nitrogen, or carbon dioxide. Phosphorous oxide is a comparatively stable substance up to temp. of about 200°. When heated in a sealed tube, the clear liquid becomes turbid at about 210°, and at a somewhat higher temp. the solid substance which separates out gradually becomes yellow, and ultimately dark red. At 300°, a considerable quantity of the red solid is formed, but there is still a large proportion of the liquid undecomposed, even after an hour's heating at this temp. At the temp. of boiling sulphur, 440°, the whole of the oxide is decomposed into solid products—red phosphorus and phosphorus tetroxide: $2P_4O_6=3P_2O_4+2P$. J. Ogier estimated for the **heat of formation,** $\frac{1}{2}(P_2O_3)=122{\cdot}1$ Cals.; and M. Berthelot, $(P,\frac{1}{2}O_3)=\frac{1}{2}P_2O_3+37{\cdot}4$ Cals. These values are quite unreliable.

A. Strecker, and A. Irving showed that white phosphorous oxide, prepared by the slow burning of phosphorus, quickly turns yellow, and ultimately red on exposure to sunlight. It is assumed that the phosphorous oxide is itself decomposed: $5P_2O_3=4P+3P_2O_5$. R. Cowper and V. B. Lewes attributed (i) the colour change; and (ii) the spontaneous inflammation which occurs when the oxide is thrown into the air, to the presence of finely-divided phosphorus associated as an impurity with the phosphorous oxide—*vide supra.* T. E. Thorpe and A. E. H. Tutton showed that phosphorous oxide obtained by their mode of preparation slowly becomes yellow in diffused daylight and rapidly in sunlight. About 0·8 to 1·0 per cent. of red phosphorus may be produced in 4 to 6 months' exposure. Fig. 32 shows the intensity of the colour change which occurred when a tube was placed in the solar spectrum for 3 hrs. The dotted curve is supposed to represent the sensitiveness of the oxide to change in diffcrent parts of the spectrum. The maximum change occurs between the F- and the G-lines. If the reddened oxide be melted, filtered, and distilled, it is again reddened by light, but if these operations be repeated four times, the product remained clear and colourless after 12 months' exposure. The insensitive oxide has not been obtained by distillation at ordinary temp. in vacuo, but isolated crystals may be found which have not reddened in light. The **index of refraction,** μ, for light of wave-length λ, at 27·4°, is:

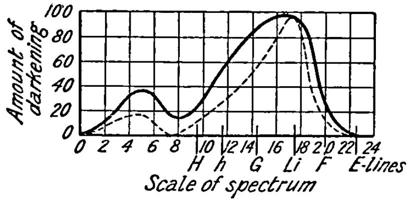


Fig. 32.—The Effect of Different Parts of the Spectrum on the Colour Change of Phosphorous Oxide.

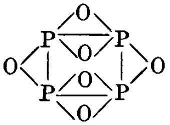
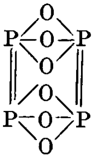
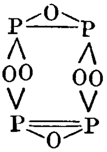
	Li-line.	C-line.	D-line.	Tl-line.	F-line.	G-line.
λ .	6705	6562	5892	5348	4861	4340
μ .	1·5350	1·5358	1·5403	1·5454	1·5518	1·5616

The results at 27·4° were represented by $\mu=1{\cdot}5171+817670\lambda^{-2}-316590000000\lambda^{-4}$. The **refraction equivalent** for the A-line is 60·5, and for the ray of infinite wave-length, 58·9. F. Zecchini calculated 21·4 for the mol. refraction with the μ-formula, and 14·25 with the μ^2-formula. H. J. Emeléus found the spectrum of glowing phosphorous oxide is the same as that of burning and of glowing phosphorus—*vide supra*, the oxidation of phosphorus. T. E. Thorpe and A. E. H. Tutton found the **dispersion** for the *H*- and *A*-lines to be 0·0366, and the **dispersion equivalent,** 4·17. O. Stelling studied the X-ray spectrum. The sp. **magnetic rotation** at 24·75° is 1·5832, and the mol. magnetic rotation 9·962. This agrees with the general rule that free phosphorus has a larger value than when combined with oxygen. R. Schenck and co-workers found the sp. **electrical conductivity** of phosphorous oxide at 25° to be $1{\cdot}2\times10^{-7}$, and the **dielectric constant,** 3·2 at 22°.

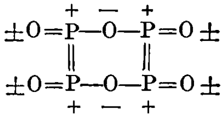
Analyses by J. J. Berzelius, H. Davy, T. Thomson, P. L. Dulong, and T. E. Thorpe and A. E. H. Tutton are in agreement with the empirical formula P_2O_3; and the vapour density and cryoscopic observations with P_4O_6. The observations on the sp. vol. indicate that the oxygen atoms are joined to the phosphorus atom by single linkages, and that the phosphorus atom is quinquevalent. This gives as possible formulæ:







H. Henstock gave for the electronic structure:



$$\begin{array}{ccccccccc} & & + & & - & & + & & \\ \pm O & = & P & - & O & - & P & = & O\pm \\ & & \| & & & & \| & & \\ \pm O & = & P & - & O & - & P & = & O\pm \\ & & + & & - & & + & & \end{array}$$

Since it has been shown that the vapour of phosphorus in air is mainly phosphorous oxide, the physiological action of phosphorus vapour is really that of the vapour of phosphorous oxide. F. Wöhler and F. T. Frerichs, P. Schulz, J. Personne, B. von Dybkowsky, etc., have discussed the toxic action of phosphorous oxide. According to T. E. Thorpe and A. E. H. Tutton, **hydrogen** has no action on hot or cold phosphorous oxide; but when exposed to **air** or **oxygen,** spontaneous oxidation to phosphorus pentoxide occurs. When a few decigrams of phosphorous oxide are placed at the bottom of a wide tube closed at one end, and previously filled with dry oxygen, and the tube sealed and kept in the dark, in an upright position, a bulky, snow-like deposit of pure phosphoric oxide is formed in rhythmic striæ or annuli along the walls of the tube, showing that vaporization of the phosphorous oxide precedes its oxidation. The action is comparatively slow at first, but seems to proceed at an accelerated rate as the press. of the included oxygen diminishes, whereby the volatility of the phosphorous oxide is increased. Under diminished press. the tube becomes more or less filled with a luminous fluctuating glow, which instantly stops when the press. is increased to that of the atm. By increase of temp., effected by warming the outside of the tube with a water-jacket, the diminution of press. required to produce the glow becomes less—a further proof that the glow is due to the action of oxygen on the *vapour* of phosphorous oxide. If the temperature is gradually raised to about 70°, the rate of volatilization, and consequent oxidation, is such that the mass of phosphorous oxide burns, but the vigorous combustion can be at once stopped by reducing the press. of the oxygen, and immediately renewed by restoring the press., and the experiment can be repeated until the whole of the oxide or the oxygen is used up. The change from glow to actual flame is perfectly regular and gradual, and is unattended with any sudden increase in brilliancy. No ozone is formed as the oxidation proceeds. This fact supports the assumption that the formation of ozone during the glow of phosphorus is caused by the dissociation of the oxygen mol. in the formation of phosphoric oxide: $P_2+3O_2=P_2O_5+O$, and $O+O_2=O_3$. When phosphorous oxide is converted into the pentoxide, no dissociation of oxygen mols. need be assumed to occur: $P_4O_6+2O_2=2P_2O_5$. These phenomena are so very similar to those which occur with phosphorus alone that it might be thought that the glow observed in the case of phosphorous oxide is due to the presence of free phosphorus in that compound. The amount of free phosphorus required to produce a glow is so very small that the supposition cannot be at once dismissed as impossible. The absence of the ozone and the gradual increase in the intensity of the glow, until it passes into steady combustion as the temp. is increased, seem convincing that phosphorous oxide phosphoresces in contact with oxygen like phosphorus itself, and under very similar conditions. Moreover, no hydrogen dioxide could be detected when the glow occurred in moist air, whereas the glow of phosphorus under the same conditions is attended with the production of notable quantities of that substance. E. Jungfleisch, R. Schenck and co-workers, E. Scharff, L. and E. Bloch, H. B. Weiser and A. Garrison, and E. Gilchrist attributed the luminescence of phosphorus entirely to the oxidation of phosphorus trioxide. W. E. Downey showed that light from oxidizing phosphorus trioxide, like that from phosphorus, is capable of ionizing oxygen; and H. J. Emeléus, that the spectra of glowing phosphorus, phosphorus trioxide, and burning phosphine are the same. H. Rinde inferred that in dry oxygen, phosphorus trioxide is oxidized directly to the pentoxide without glow, but in moist oxygen, an intermediate compound, possibly phosphine, is formed. C. C. Miller also showed that water-vapour is necessary for the glow; and that phosphine is always formed, and liquid phosphorus hydride as well. The production of this liquid accounts for the rise of press. to a maximum when phosphorus trioxide is in the presence of water-vapour at 2·5 to 5·0 mm. press. The subsequent fall of press. is attributed to the interaction of phosphorus hydride and trioxide. At 25°, in oxygen at 600 mm., and in the presence of water-vapour, the phosphorus oxidizes directly to the tetroxide, not the pentoxide. W. E. Downey showed that ozone is formed during the oxidation of the trioxide; this is taken to mean that oxygen is oxidized by the light of the glow which has the wave-length $\lambda=1200$ A. to 1800 A.

Melted phosphorous oxide readily takes fire in the air, especially when gently warmed or when spread out over the surface of paper or cloth. Thrown into oxygen heated to 50° or 60°, it instantly ignites with a flame of almost blinding brilliancy. Great care is necessary to exclude air from the apparatus during the process of distillation of phosphorous oxide. If air is permitted to enter the distilling vessel, the vapour of the oxide at once ignites, and may set fire to the liquid, with the possibility of a dangerous explosion. According to R. Schenck and co-workers, dry oxygen has scarcely any action on phosphorous oxide at 10°; 40° is the most favourable temp. for measuring the speed of oxidation which is then proportional to the square root of the press. of the oxygen. This is taken to mean that the reaction is semi-molecular, and is effected by atoms—*vide supra*, oxidation of phosphorus. When air charged with **ozone** is passed over a small quantity of phosphorous oxide, the oxide glows continuously, without the pulsating appearance which characterizes its glow in air or in oxygen under diminished press. The glow ceases when the silent discharge is interrupted, but recommences immediately it is resumed. The glow in the case of the ozonized oxygen, at atm. press., is close to the oxide, and not, as in the case of air, or in rarefied oxygen, at some distance away from it. Moreover, after a time, owing apparently to the energy of the reaction, the phosphorous oxide melts, whereas it never melts in pure oxygen or in air at the ordinary temp.

Phosphorous oxide was formerly stated to deliquesce rapidly in air, and to dissolve in **water** with a hissing noise; indeed, J. J. Berzelius said that the attraction of the anhydride for the moisture of the air develops so much heat that the oxide takes fire. The ignition of phosphorous oxide when shaken in air was shown by R. Cowper and V. B. Lewes to be due to the presence of very finely-divided yellow phosphorus —*vide supra*—and the hissing noise developed by contact with water is probably due to the presence of phosphorus pentoxide, because T. E. Thorpe and A. E. H. Tutton found that phosphorous oxide is somewhat inert in its attraction for water. Both the solid and the liquid form dissolve only with great slowness; a few grams will remain for several days in contact with water without any considerable diminution in bulk being apparent. On long standing, the pure oxide completely dissolves; the soln. has a strong acid reaction and an alliaceous smell; and its general properties show that phosphorous oxide is slowly converted into phosphorous acid by the action of cold water. When a small quantity of water, not lower than 15° in temp., is added to a quantity of phosphorous oxide, not less than one-sixth its bulk, the slight rise of temp., probably due to the formation of phosphorous acid at the surface of contact, is just sufficient after about 10 minutes to melt the oxide which remains unmixed with the water at the bottom of the vessel. This slowly dissolves, as above described, and in a few days forms a soln. of phosphorous acid. When the water is heated, the reaction is entirely different. At temp. below 100°, it is very energetic; large quantities of red phosphorus or the red suboxide are formed with an explosive evolution of spontaneously inflammable phosphoretted hydrogen and the formation of phosphoric acid. With quantities of phosphorous oxide exceeding a couple of grams, hot water produces most violent explosions. A cold dil. soln. of **alkali hydroxide** resembles cold water in its action on phosphorous oxide. No action is apparent at first, but, on standing, the oxide is dissolved, and a phosphite is formed. Cold conc. or hot dil. soln. decompose the oxide with production of red phosphorus, or the tetritoxide, and a phosphate, whilst spontaneously inflammable phosphine is evolved. When phosphorous oxide is thrown into a jar of **chlorine,** it instantly ignites, and burns with a greenish flame. In a slow current of dry chlorine, the oxide becomes very hot, and burns with a pale green flame scarcely perceptible in daylight. If the flask containing the phosphorous oxide is surrounded by ice, and the current of chlorine is not too rapid, the whole of the oxide is gradually converted into a clear liquid which does not solidify in cold water. On distilling this liquid, the thermometer rises rapidly to 107°, and remains constant at this temp. for some time, after which it suddenly rises to 200°, and the residue in the flask becomes viscid. The condensate is phosphoryl chloride, and the viscid residue is metaphosphoryl chloride, PO_2Cl, and the reaction is therefore symbolized: $P_4O_6+4Cl_2=2POCl_3+2PO_2Cl$. Phosphorous oxide reacts violently with liquid **bromine,** and the mass generally inflames. When the oxide at ordinary temp. is continuously acted on by bromine vapour, lemon-yellow crystals of phosphorus pentabromide are formed above the oxide, while the oxide itself becomes covered with a white amorphous powder of phosphorus pentoxide: $5P_4O_6+20Br_2=8PBr_5+6P_2O_5$. The crystals of the pentoxide afterwards dissolve in the excess of bromine which condenses on them, the pentabromide is washed down, and a second reaction occurs resulting in the formation of phosphoryl bromide, and metaphosphoryl bromide: $P_4O_6+4Br_2=2POBr_3+2PO_2Br$, as in the case of chlorine. Phosphorous oxide reacts slowly with **iodine,** forming an orange-red solid. Even when the substances are heated together in a sealed tube at 150°, the reaction is far from complete. When the two substances are heated, under press., with a quantity of carbon bisulphide, phosphoric oxide is formed, and orange-red prisms of P_2I_4 separate out from the conc. soln. No formation of the tri-iodide could be detected. The main reaction is probably in accordance with the equation $5P_4O_6+8I_2=4P_2I_4+6P_2O_5$. Phosphorous oxide rapidly absorbs **hydrogen chloride,** forming a viscous mass and a clear, mobile liquid. The semi-solid substance is at first quite white, but as the reaction proceeds it changes to yellow and orange. The clear liquid consists of phosphorus trichloride, boiling at 76°; the semi-solid residue is, for the most part, soluble in water, and the soln. contains phosphorous and phosphoric acids. The yellow solid was free phosphorus. The main reaction is symbolized: $P_4O_6+6HCl=2PCl_3+2H_3PO_3$; and the phosphorous acid reacts with the trichloride as symbolized by A. Geuther: $PCl_3+4H_3PO_3=3H_3PO_4+2P+3HCl$.

When phosphorous oxide and **sulphur** are heated together in an atm. of nitrogen or carbon dioxide, the two substances melt, and form separate layers of liquid; at about 160° a violent reaction occurs, no gas is produced, but the liquid becomes solid owing to the direct addition of sulphur, forming phosphorus disulphotrioxide, analogous to phosphorus pentoxide: $P_4O_6+4S=P_4O_6S_4$. The reaction with **selenium** appears to be similar to that with sulphur, but the phosphorous oxide itself is largely decomposed at the temp. of the reaction. Phosphorous oxide does not react with **sulphur dioxide**, hot or cold. The vapour of **sulphur trioxide** reacts with phosphorous oxide at ordinary temp., forming sulphur dioxide and white flocks of phosphorus pentoxide; no compound was detected other than the products of the oxidation of phosphorous oxide at the expense of the sulphur trioxide. When conc. **sulphuric acid** is dropped on phosphorous oxide there is a great rise of temp., and sulphur dioxide is liberated and the phosphorous oxide becomes oxidized to phosphoric acid. When quantities of a gram and upwards are employed, the reaction is so violent that the mass generally ingnites. **Sulphur chloride**, S_2Cl_2, acts with great violence on phosphorous oxide, forming phosphoryl and thiophosphoryl chlorides, free sulphur, and sulphur dioxide: $P_4O_6+6S_2Cl_2=2POCl_3+2PSCl_3+2SO_2+8S$. H. Prinz said that no reaction occurs even at 230°.

According to T. E. Thorpe and A. E. H. Tutton, **nitrogen** has no action on hot or cold phosphorous oxide; but **ammonia** slowly reacts in the cold, absorbing between 7 and 8 mols. of gas per mol. of oxide. When ammonia is led over phosphorous oxide melted by the warmth of the hand, in an apparatus previously filled with nitrogen, a somewhat violent reaction occurs with production of a white cloud; the mass ignites, and a considerable quantity of amorphous phosphorus or the red suboxide is formed. The violence of the reaction may, however, be controlled by surrounding the flask with iced water. The reaction is more easily regulated if the phosphorous oxide be dissolved in ether or benzene. There is formed phosphorous diamide, $HO.P(NH_2)_2$ (*q.v.*). The **substituted ammonias** react similarly. Phosphorous oxide does not react with **nitric oxide**—hot or cold, but with **nitrogen peroxide** it forms phosphorus pentoxide and the lower oxides of nitrogen. No compound of nitrogen peroxide and phosphorous oxide is formed. Phosphorous oxide does not react with **phosphine**—hot or cold. At ordinary temp., **phosphorus trichloride** and phosphorous oxide are miscible without reaction, and they can be separated by distillation; if the mixture be heated in a sealed tube at 180° for some hours, there is formed, not phosphoryl chloride, but a mixture of red phosphorus and phosphorus pentoxide and pentachloride. The reaction between **phosphorus pentachloride** and trioxide is violent at ordinary temp., forming a product which is liquid when the vessel is cooled by ice: $P_4O_6+6PCl_3=6POCl_3+4P$. According to L. Amat, phosphorous oxide and **phosphorous acid** react when heated forming solid hydrogen diphosphide. F. Krafft and R. Neumann found that when **arsenic** is heated with phosphorous oxide for 6 hrs. in an atm. of carbon dioxide in a sealed tube at 290°, the arsenic quantitatively displaces the phosphorus: $4As+P_4O_6=4P+As_4O_6$; **antimony** acts similarly.

Cold or warm phosphorous oxide was found by T. E. Thorpe and A. E. H. Tutton to have no action on **ethylene, carbon monoxide, carbon dioxide,** or **cyanogen.** The oxide dissolves without reaction in **carbon disulphide, benzene, chloroform,** and **ether.** Although phosphorous oxide reacts very slowly with water at ordinary temp., it ignites when brought in contact with **ethyl alcohol**; and by allowing the reaction to proceed gradually in a well-cooled vessel, diethyl phosphite is formed: $P_4O_6+8C_2H_5OH=2H_2O+4(HO)P(OC_2H_5)_2$, a reaction studied by T. E. Thorpe and B. North.

§ 17. Phosphorous Acid

As indicated in connection with phosphorous oxide, **phosphorous acid,** H_3PO_3, must have been known for a long time as a product of the slow oxidation of phosphorus in moist air. In 1777, B. G. le Sage[1] described the character of an acid which he obtained from the products of the slow combustion of phosphorus, and which had properties somewhat different from A. L. Lavoisier's phosphoric acid. This acid liquid was at first confused with phosphoric acid, since it was assumed that different acids were obtained by the slow and rapid combustion of phosphorus; the one was at first called *acidum phosphori per deflagrationem,* and the other *acidum phosphori per deliquium.* These two acids were later distinguished as *acide phosphorique* and *acide phosphoreux.* B. G. le Sage obtained the liquid by exposing sticks of phosphorus to moist air and collecting the liquid which was formed. The stick of phosphorus was very liable to inflame owing to the too rapid oxidation; to avoid this B. Pelletier enclosed each stick of phosphorus in a glass tube. In B. Pelletier's process for making phosphorous acid by the slow oxidation of phosphorus, each pencil of phosphorus was contained in a glass tube drawn out at one end to a fine orifice. These glass tubes, to the number of 30 or 40, were placed in a funnel the beak of which was passed into a bottle standing in a plate of water, and the whole was covered with a bell-glass with inlet and outlet for a small current of air. The phosphorus slowly oxidized, and the product deliquesced and dripped into the bottle. C. F. Bucholz placed the sticks of phosphorus in the upper part of an inclined shallow dish kept at a temp. not exceeding 10°. The acid accumulates in the lower part of the dish, and amounted to over five times the weight of the phosphorus employed. Various ways of conducting this experiment have been discussed by A. Sommer, H. A. von Vogel, T. Salzer, P. Drawe, C. Bansa, and A. Rosenheim and co-workers—*vide infra,* hypophosphoric acid. The liquid obtained by B. Pelletier was at first regarded as a special acid and called *l'acide phosphatique—phosphatic acid.* U. J. J. Leverrier, indeed, suggested that this acid is a compound of phosphoric oxide and acid. As H. Davy expressed it in 1812, the acid *per deliquium* is a combination of phosphorous oxide and the aq. vap. of the air, and does not occur in air artificially dried. He added that the liquid is a mixture of phosphorous and phosphoric acids. P. L. Dulong, and

L. J. Thénard tried to show that the process of oxidation comes to a standstill when a certain proportion of phosphoric acid has been formed; but M. Pagels could not detect any such stationary stage—given sufficient time, the oxidation proceeds to the extreme limit. H. Davy's observation that ordinary phosphatic acid is a mixture of phosphorous and phosphoric acids was confirmed; and P. L. Dulong, and A. Sommer found that the liquid contains these two acids in the approximate proportion 1 : 4. H. Davy further observed that while solid phosphorus pentachloride reacts with water giving phosphoric acid, liquid phosphorus trichloride yields a syrupy liquid which crystallizes slowly on cooling, forming a substance with very singular properties and which "may be called *hydrophosphorous acid;* for it consists of pure phosphorous acid and water." H. Davy examined the properties of phosphorous acid; and its relations with the hypophosphorous and phosphoric acids were established by P. L. Dulong in 1816.

J. J. Berzelius made phosphorous acid by treating phosphorous oxide with water —a reaction studied by T. E. Thorpe and A. E. H. Tutton, *vide supra.* B. D. Steele obtained it by the action of iodine on hypophosphorous acid (*q.v.*) in the presence of mineral acids; and A. Besson, by heating the hemioxide with water in a sealed tube at 100°: $P_2O+O_2+3H_2O=2H_3PO_3$. Phosphorous acid is also produced by the action of hot dil. nitric acid on phosphorus; the objection to this process, said J. Corne, is the simultaneous production of phosphoric acid (*q.v.*), and this the more, the greater the conc. of the nitric acid. T. Salzer, and J. Philipp also reported that some hypophosphoric acid is produced at the same time. The early workers knew that the aq. soln. of phosphatic acid slowly decomposes, giving off phosphine, hence the faint smell like garlic. C. F. Schönbein mentioned that freshly prepared phosphatic acid contains a trace of nitric acid as well as ozone. A. Tamm also observed that some phosphorous acid is formed when phosphated steel is dissolved in nitric acid.

According to A. Oppenheim, phosphorous acid is formed when ordinary phosphorus is heated with conc. sulphuric acid in a sealed tube at 200°; some sulphur dioxide is simultaneously produced; and R. Rother, and A. L. Ponndorf observed its formation during the action of sulphur dioxide on hypophosphorous acid: $2H_3PO_2+SO_2=S+2H_3PO_3$. H. Schiff, R. M. Bird and S. H. Diggs, and O. J. Walker observed that some phosphorous acid is produced when a sat. soln. of cupric sulphate is allowed to act on yellow phosphorus while protected from air. Phosphorous acid is formed when hypophosphorous acid (*q.v.*) is oxidized by many metal oxides or salt soln. Thus, R. Engel observed this to occur during the action of that acid on palladium salts; and O. J. Walker on silver nitrate soln. According to A. Michaelis, and A. Besson, in H. Davy's mode of preparing phosphorous acid by the action of water on phosphorus trichloride, the reaction with water is quite a complicated one; the former imagined the reaction to involve the trio: (i) $PCl_3+H_2O=POCl_3+H_2$; (ii) $POCl_3+H_2=PCl_2(OH)+HCl$; and (iii) $PCl_2(OH)+2H_2O=H_3PO_3+2HCl$. A. Droquet recommended the following modification of H. Davy's process so as to avoid the special preparation of trichloride beforehand:

> A cylinder, 30 cms. long and 2·5 cms. in diameter, was one-quarter filled with phosphorus, and three-quarters with water, and then heated to the m.p. of the phosphorus. Chlorine was then passed into the cylinder by means of a tube reaching to the bottom. The chlorine fires the phosphorus, forming the trichloride which is decomposed by the superincumbent water. When the water is saturated with acid it is replaced by fresh water. The phosphorus must be kept in excess, or the pentachloride will be formed and the product accordingly be contaminated with phosphoric acid. J. Corne did not recommend this process because the formation of phosphoric acid cannot be avoided.

H. Grosheintz recommended rapidly passing the vap. of phosphorus trichloride at 60° in a current of dry air through two wash-bottles each containing 100 c.c. of water at 0°. In about 4 hrs., the contents of the first wash-bottle is a mush of crystals which can be drained, washed with ice-cold water, and dried in vacuo.

The mother-liquid is returned to the wash-bottle. T. Milobendzky and M. Friedman avoided the violent reaction of phosphorus trichloride and water in the preparation of phosphorous acid, by using conc. hydrochloric acid in place of water. Phosphorous acid is formed when several other phosphorous halides—PBr_3, PI_3, P_2I_4, etc.—are decomposed by water or by compounds which contain the elements of water; thus, A. J. Balard showed that it is formed by the action of water on the tribromide; L. Hurtzig and A. Geuther, by the action of phosphorous trichloride on oxalic acid heated in a flask fitted with a reflux condenser: $PCl_3+3H_2C_2O_4=H_3PO_3+3CO+3CO_2+3HCl$; and A. Geuther, by warming phosphorus trichloride with phosphoric acid: $PCl_3+3H_3PO_4=3HPO_3+H_3PO_3+3HCl$, or pyrophosphoric acid: $PCl_3+3H_4P_2O_7=6HPO_3+H_3PO_3+3HCl$—some red phosphorus may be formed at the same time.

D. Amato showed that some phosphorous acid is formed during the decomposition of spontaneously inflammable phosphine: $2PH_3+3O_2=2H_3PO_3$; H. J. van de Stadt studied the conditions favourable for this reaction—*vide supra*, phosphine. A. Besson found that phosphorous acid is formed when sulphuryl chloride reacts with phosphine; T. E. Thorpe and A. E. H. Tutton, when hydrochloric acid acts on phosphorous diamide: $HOP(NH_2)_2+2HCl+2H_2O=2NH_4Cl+H_3PO_3$; and A. Damoiseau, when yellow phosphorus acts on hydriodic acid: $2P+HI+3H_2O=H_3PO_3+PH_4I$.

H. Davy obtained crystals of phosphorous acid by evaporating the aq. soln. to a thin syrupy liquid, and cooling it; P. L. Dulong, and C. A. Wurtz evaporated the soln. until decomposition began, and allowed the mass to stand in vacuo for a few days. H. Rose, and C. F. Rammelsberg found that the thin syrup crystallized easier than the thick one. J. Thomsen evaporated the liquid with the temp. slowly rising to 180°, and found that the syrupy liquid on cooling crystallized in a few hours—often in a few minutes. If the liquid be seeded with a crystal of the acid, the cold or undercooled liquid crystallizes very quickly.

The white or grey mass consists of colourless crystals. According to J. Thomsen,[2] the fused acid has a sp. gr. 1·651 at 21·2°. L. Hurtzig gave 74° for the m.p., and J. Thomsen, 70·1°. For the m.p. of mixtures of phosphorous and phosphoric acids, *vide* Fig. 33. H. Davy found that the crystals, or conc. soln., decompose when heated into phosphine and phosphoric acid. P. Vigier represented the reaction by $4H_3PO_3=3H_3PO_4+PH_3$; and L. Hurtzig and A. Geuther found that some red phosphorus may be formed by rapidly heating the acid. N. R. Dhar found that the decomposition of phosphorous acid into phosphine and phosphoric acid is retarded by mild reducing agents. The mol. lowering of the f.p. was found by F. M. Raoult to be 2·39°; S. Arrhenius gave 2·6°–3·0°. A. Italiener measured the lowering of the f.p. and the raising of the b.p. of water by phosphorous acid, and found that if C represents the molar conc. of H_3PO_3 per litre, $\delta\theta$, the observed depression of the f.p., or the observed rise in the b.p.; k, the ionization constant assuming the molecule is H_3PO_3, and k_2, the constant on the assumption that the molecule is $(H_3PO_3)_2$; and i_1 and i_2 the corresponding association factors:

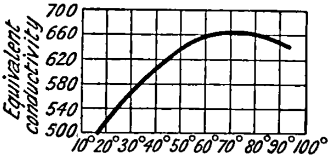

FIG. 33.—The Effect of Temperature on the Electrical Conductivity of Phosphorous Acid

	Freezing Solutions.					Boiling Solutions.			
C	1·186	0·539	0·296	0·148	C	0·976	0·488	0·244	0·122
$\delta\theta$	2·941°	1·538°	0·835°	0·455°	$\delta\theta$	0·51°	0·28°	0·16°	0·13°
k_1	20·98	25·96	28·18	30·70	k_1	5·23	8·74	6·56	10·56
i_1	1·128	1·143	1·515	1·650	i_1	0·969	1·063	1·215	1·972
k_2	41·96	51·92	56·36	61·40	k_2	10·26	11·48	13·12	21·30
i_2	2·256	2·286	3·030	3·210	i_2	1·938	2·126	2·430	3·944

With the lowering of the f.p., if the molecules are simply H_3PO_3, then in the less dil. soln. ionization occurs $H_3PO_3 \rightleftharpoons H^{\cdot}+H_2PO_3{}'$, and with the more dil. soln.,

$H_3PO_3 \rightleftharpoons 2H^{\cdot}+HPO_3''$. In that case, i should approximate to 2 with the less dil. soln., and exceed this value with the more dil. soln. This is not the case. With the raising of the b.p., very little ionization occurs on the assumption that the mols. are simply H_3PO_3. These contradictory conclusions are explained by assuming that at least in the conc. soln. there is an equilibrium condition, $2H_3PO_3 \rightleftharpoons (H_3PO_3)_2$; and that the complex mol. is partially ionized, $H_6P_2O_6 \rightleftharpoons H^{\cdot}+H_5P_2O_6'$, and $H_6P_2O_6 \rightleftharpoons 2H^{\cdot}+H_5P_2O_6''$. F. Guthrie found the eutectic temp. of acid and water to be $-1{\cdot}5°$. E. Cornec measured the lowering of the f.p. of a soln. of phosphorous acid when progressively neutralized by sodium hydroxide. As shown in Fig. 34, there are two breaks in the curve corresponding with the dibasicity of the acid. The results with phosphoric and hypophosphorous acids are shown in the same diagram for comparison. Analogous results were obtained with aq. ammonia in place of soda-lye. E. Cornec also measured the effect of the progressive neutralization of phosphorous acid with potassium hydroxide, and with aq. ammonia, the effect on the index of refraction of the soln. J. Thomsen gave 7·07 Cals. for the heat of fusion of phosphorous acid. The heat of formation of the crystallized acid, $(H_3,P,O_3)=227{\cdot}70$ Cals.; for the fused acid, 224·63 Cals.; and in aq. soln., 227·57 Cals. The heat of soln. of H_3PO_3 with an excess of water is 233 Cals., and of $H_3PO_3.3H_2O$, 152 Cals. The effect is zero with $H_3PO_3.400H_2O$. The heat of neutralization for $nH_3PO_{3aq.}+NaOH_{aq.}$ is 149 Cals. for $n=2$; 148 Cals. for $n=1$; 142 Cals. for $n=\frac{1}{2}$; and 96 Cals. for $n=\frac{1}{3}$. L. Amat gave $H_3PO_3+NaOH=NaH_2PO_3+H_2O_{solid}+25{\cdot}2$ Cals.; $H_3PO_3+2NaOH=Na_2HPO_3+2H_2O_{solid}+41{\cdot}6$ Cals.; and $H_3PO_{3aq.}+NaOH_{aq.}=NaH_2PO_{3aq.}+H_2O_{liquid}+14{\cdot}85$ Cals. P. A. Favre and J. T. Silbermann gave for the calorimetric eq. of phosphorous, phosphoric, and hypophosphorous acids, 2·91 : 4·36 : 1; and for the heat of oxidation, 140·394 Cals.

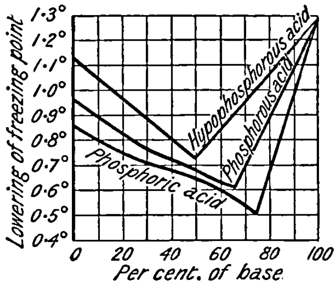

FIG. 34.—Effect of the Progressive Addition of some Phosphorous Acids to Sodium Hydroxide on the Lowering of the Freezing Point of the Solution.

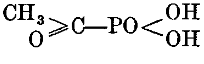
F. Zecchini gave for the refraction eq. 26·04 with the μ-formula, and 15·17 with the μ^2-formula. O. Stelling measured the X-ray K-absorption spectrum of phosphorous acid, and of its salts and di-esters, and found that the results agree with the assumption that the phosphorus is tervalent with the solids, and tautomeric quinque- and ter-valent in soln. Phosphorous acid, the di-esters, methyl phosphorous acid, and ferric monopropyl phosphate have the structure $(RO)_2 : PO.H$; sodium diethyl phosphite, $(C_2H_5O)_2 : PO.Na$; silver diethyl phosphate, $(C_2H_5O)_2 : PO.OAg$; and monoacetyl phosphorous acid:



$$\left.\begin{matrix}CH_3\\O\end{matrix}\right\rangle C{-}PO\left\langle\begin{matrix}OH\\OH\end{matrix}\right.$$

A. Miolati and E. Mascetti measured the effect of progressive addition of sodium hydroxide and of ammonia on the sp. conductivity of phosphorous acid. W. Ostwald gave for the mol. conductivity, μ, at 25°, for soln. with a mol of the acid in v litres:

v	2	4	8	16	32	64	128	256	512	1024
μ	129	156	187	222	252	292	318	337	351	358

He represented the effect of temp. on the conductivity of normal soln. by Fig. 34. Observations were also made by A. Italiener, and A. Rosenheim and J. Pinsker. Comparing the results with the different phosphorus acids:

v		16	32	64	128	256	512	1024
μ	Phosphoric acid	124	156	195	240	279	317	341
	Hypophosphoric acid	184	199	222	246	275	304	370
	Phosphorous acid	222	257	292	318	337	351	358
	Hypophosphorous acid	245	281	312	335	352	361	367

A. Italiener gave for the hydrogen-ion conc. of soln. in which normality is represented by 37·84 grms. of the acid per litre:

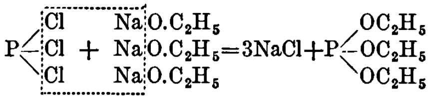
	N-	0·5*N*-	0·25*N*-	0·1*N*-	0·01*N*-	0·005*N*-
$[H^{\cdot}]$.	0·2337	0·1303	0·0931	0·04198	0·005984	0·002877

E. Blanc calculated for the ionization of constants of phosphorous acid $K_1=0\cdot05$, and $K_2=2\cdot4\times10^{-5}$. I. M. Kolthoff found that the first ionization constant K_1 increases from 0·016 in 0·001*M*-soln. to 0·062 in 0·1*M*-soln.; and the second ionization constant K_2, calculated from the $H^{\cdot}$-ion conc. of mixtures of a secondary phosphite with hydrochloric acid is $0\cdot0_67$ at 18°. The first stage of phosphorous acid titration may be conducted with methyl-orange as indicator using a comparison soln. with $p_H=3\cdot85$. A sharp end-point for the second stage is obtained with thymolphthalein as indicator. For the anodic oxidation of the phosphites, *vide infra*, perphosphates. P. Pascal studied the magnetic properties.

Analyses of the acid by H. Davy,[3] and H. Rose agree with the formula H_3PO_3. C. A. Wurtz found that the acid behaves as if it were bibasic. This makes it almost certain that two of the hydrogen atoms are similarly disposed in the molecule, and differently from the third hydrogen atom. Accordingly, A. Lieben, F. C. Palazzo and F. Maggiacomo, and L. Amat inferred that the phosphorus is quinquevalent and is associated with only two hydroxyl groups, $O=PH(OH)_2$, and not $P(OH)_3$, where the phosphorus would be tervalent. T. Graham supposed the acid to be tribasic; and in support of this, C. Zimmermann mixed a soln. of 6 mols of sodium hydroxide with one containing a mol of phosphorous acid, and, by adding absolute alcohol, precipitated a very viscid liquid, which was washed with alcohol until all the soda was removed. He said that considering the properties of the other alkaline phosphites it is not surprising that the viscid liquid cannot be crystallized. The soln. is strongly alkaline, and readily reduces soln. of silver salts. The ratio P : Na in the product was 1 : 3, and hence it was inferred that the soln. contained Na_3PO_3. L. Amat, however, was unable to verify this, for the only salt he could obtain was $OPH(ONa)_25H_2O$. V. Auger's attempts to prepare normal sodium phosphite, Na_3PO_3, by the action of excess of sodium ethoxide on an alcoholic soln. of phosphorous acid were unsuccessful, sodium hydrophosphite, Na_2HPO_3, being the only product. The dibasicity of the acid with respect to sodium hydroxide is in agreement with J. Thomsen's observations, who found that with 1, 2, and 3 mols of the sodium hydroxide per mol of phosphorous acid, respectively 14·8, 28·4, and 28·9 Cals. of heat were evolved, increasing the proportion of alkali beyond that corresponding with the formation of Na_2HPO_3 produces no marked thermal effect, indicating that no further reaction ensues. The results with pyrophosphoric, sulphuric, sulphurous, boric, carbonic, and other acids agree with the basicities usually assigned to them. Consequently, if the mol. wt. of an acid be known, its probable basicity can be deduced from observations on the heat evolved when it is neutralized step by step by means of an alkali. With metaphosphorous acid the results appear exceptional, for they indicate a monobasic acid; this is explained by assuming that the aq. soln. of metaphosphorous acid is unstable because it forms the ortho-acid. According to L. Amat, phosphorous acid is monobasic with methyl-orange; and dibasic with phenolphthalein and Porrior's sulphur-blue; and, according to A. Italiener, monobasic with methyl-orange, and dibasic with *p*-nitrophenol, and α-naphthophthalein. It exerts a slight reducing effect on *p*-nitrophenol.

Phosphorous oxide is considered to be the anhydride of phosphorous acid; but R. Reinitzer—*vide supra*, oxidation of phosphorus—raised the question whether this is really the case of the behaviour of the oxide when treated with water. It is not possible to say definitely whether the formula of phosphorous acid should be written $P(OH)_3$, or $OPH(OH)_2$, since the evidence from different sources appears contradictory when examined from different angles. The formation of the acid from phosphorus trichloride points to the formula $P(OH)_3$, and the dibasicity of the acid to the formula, $O:PH(OH)_2$. The latter formula appears the more probable.

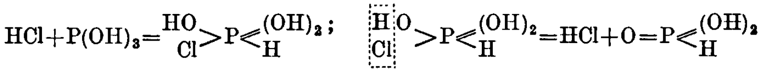
Under special conditions, the hydrogen directly attached to the phosphorus atom may have acidic properties, in the same way that the hydrogen of ammonia can be replaced by other radicles. Two isomeric *triethyl phosphites* have been prepared, by R. Railton, C. Zimmermann, A. E. Arbusoff, T. E. Thorpe and B. North; and by A. Michaelis and co-workers. The one obtained by the action of sodium ethoxide on phosphorus trichloride is supposed to be constituted $P(OC_2H_5)_3$, in accord with the equation:



$$\mathrm{P}\!\left\langle\begin{array}{l}\mathrm{Cl}\\ \mathrm{Cl}\\ \mathrm{Cl}\end{array}\right. + \begin{array}{l}\mathrm{Na\,O.C_2H_5}\\ \mathrm{Na\,O.C_2H_5}\\ \mathrm{Na\,O.C_2H_5}\end{array} = 3\mathrm{NaCl}+\mathrm{P}\!\left\langle\begin{array}{l}\mathrm{OC_2H_5}\\ \mathrm{OC_2H_5}\\ \mathrm{OC_2H_5}\end{array}\right.$$

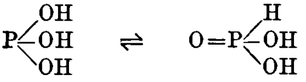
It is accordingly referred to as symmetrical ethyl phosphite. It is a liquid with a sp. gr. 0·9605 at 17°, it boils at 49° and 8–9 mm., and reduces soln. of mercuric chloride. The other is obtained by the action of ethyl alcohol on phosphorous oxide, or by treating lead phosphite with ethyl iodide. It is a liquid of sp. gr. 1·028 at 21°; it boils at 198° and 760 mm.; and does not reduce soln. of mercuric chloride. It is referred to as unsymmetrical ethyl phosphite, and is supposed to be constituted like ordinary phosphorous acid, $O=P(C_2H_5)(OC_2H_5)_2$. Phosphorous acid is prepared by a method analogous to that employed for the symmetrical acid. Hence, it is assumed that while there is a simple metathecal change when sodium ethoxide and phosphorus trichloride react, yet, in the case of water and phosphorus trichloride, it is assumed that there is an intramolecular change resulting in the formation of unsymmetrical phosphorous acid and an increase in the valency of the phosphorus.

A. E. Arbusoff assumed that symmetrical phosphorous acid is first formed: $PCl_3+3H_2O=P(OH)_3+3HCl$, where the phosphorus remains tervalent. P. Pascal's observations on the magnetic properties of the phosphites agree with the formula $P(OH)_3$. The great tendency of the compounds of tervalent phosphorus to form addition products has been emphasized by the work of A. E. Arbusoff, P. Schützenberger, C. Risler, and L. Lindet; but not so with the quinquevalent phosphorus compounds. Accordingly, A. E. Arbusoff assumes that the symmetrical phosphorus acid forms a complex $P(OH)_3HCl$ with hydrogen chloride produced by the reaction. This involves the restoration of the two latent valencies of phosphorus; the complex is unstable, then breaks down into unsymmetrical phosphorous acid without changing the valency of the phosphorus:



$$\mathrm{HCl+P(OH)_3=\begin{array}{c}HO\\ Cl\end{array}\!>\!P\!<\!\begin{array}{l}(OH)_2\\ H\end{array};\quad \begin{array}{c}H\\ Cl\end{array}\begin{array}{c}O\\ \ \end{array}\!>\!P\!<\!\begin{array}{l}(OH)_2\\ H\end{array}=HCl+O=P\!<\!\begin{array}{l}(OH)_2\\ H\end{array}}$$

This recalls the parallel case of the addition of hydrogen halides to the unsaturated hydrocarbons observed by A. P. Eltekoff. As in the case of sulphurous and nitrous acids, the facts can also be explained by assuming the desmotropic change:



$$\mathrm{P}\!\left\langle\begin{array}{l}\mathrm{OH}\\ \mathrm{OH}\\ \mathrm{OH}\end{array}\right. \rightleftharpoons \mathrm{O{=}P}\!\left\langle\begin{array}{l}\mathrm{H}\\ \mathrm{OH}\\ \mathrm{OH}\end{array}\right.$$

Symmetrical Acid. Unsymmetrical Acid.

This view is supported by A. D. Mitchell's observations on the action of water on phosphorus trichloride (*q.v.*), and by O. Stelling's observations on the K-absorption X-ray spectrum. A. Rosenheim and A. Italiener found that the depression of the f.p., and the elevation of the b.p. of aq. soln. agree with the assumption that phosphorus acid has the constitution $H_4(P_2O_6H_2)$ in complete analogy with $H_4(P_2O_7)$ for pyrophosphoric acid. There is thus a complete set of ions:

$PO_4^{\cdots}$	$HPO_3^{\cdot\cdot}$	$H_2PO_2^{\cdot}$	H_3PO	PH_4'
Phosphate.	Phosphite.	Hypophosphite.	Phosphine oxide.	Phosphonium.

G. Oddo discussed this reaction as an example of what he calls *mesoidria, i.e., mesohydry.* L. Lendle, and G. Schick inferred that barium phosphite exists in isomeric forms because of the difference in the reducing properties of the phosphites prepared at high and at low temp. The low temp. form was said to be the most active, and to it was attributed an aldolic structure; while the enolic structure was assigned to the less active form prepared at the high temp.:

$${}^{H}_{O}{\geqslant}P{<}^{O}_{O}{>}Ba$$

Aldolic barium phosphite.

$$HO{-}P{<}^{O}_{O}{>}Ba$$

Enolic barium phosphite.

The inversion from one form to the other was supposed to explain the maximum attained by the conductivity curve, Fig. 33. H. Gorke showed that there is no need for this hypothesis to explain the facts. The salt prepared at the low temp. may have a trace of impurity, say barium hydroxide, which accelerates the reduction, and that prepared at the higher temp. may be an acid salt or contain a trace of phosphoric acid which retards the reduction. H. Burgarth, H. Remy, and T. M. Lowry discussed the electronic structure of phosphorous acid—*vide supra,* phosphoric acid.

P. Schulz found that phosphorous acid or the phosphites act on the nerve centres and abdominal glands. The thermal decomposition of phosphorous acid into phosphine and phosphoric acid: $4H_3PO_3=3H_3PO_4+PH_3$—*vide infra,* phosphites—was found by N. R. Dhar to be hindered by mild reducing agents. L. Dusart said that while **hydrogen** has no reducing action on phosphorous acid, hydrogen *in statu nascendi* reduces the acid to phosphine. The crystallized acid deliquesces in air producing a colourless liquid. The conc. aq. soln., said C. A. Wurtz, should be protected from **air** on account of their tendency to take up **oxygen**; but J. L. Gay Lussac observed no tendency on the part of the phosphites to absorb oxygen from the air. R. Luther and J. Plotnikoff found that the reaction $H_3PO_3+\frac{1}{2}O_2=H_3PO_4$ is immeasurably slow in the absence of iodine as catalyst—either in darkness or in light; but in the presence of the catalyst iodine, reaction proceeds in light. The reactions involved are (i) $2HI+O=I_2+H_2O$, a change which is slow in darkness, but rapid in light; and (ii) $H_3PO_3+H_2O+I_2=H_3PO_4+2HI$, a reaction which takes place rapidly, and is not affected by light. W. Omeliansky showed that the organism which converts nitrates into nitrites does not oxidize sodium phosphite or sulphite. H. Wieland and A. Wingler found that aq. soln. of phosphorous acid do not absorb oxygen, but do so in presence of palladium black, phosphoric acid resulting. Charcoal does not act like palladium. Soln. with anhydrous, dry palladium black does not cause the absorption of oxygen in dry ethereal soln., whereas, on admitting traces of water, reaction proceeds rapidly. Similarly, palladium black, *p*-benzoquinone, and phosphorous acid do not interact in absence of water. It is therefore concluded that the reducing action of phosphorous acid is due, not to its absorption of oxygen, but to the loss of hydrogen from a *hydrate,* which is the active form: $O:PH(OH)_2\rightarrow PH(HO)_4\rightarrow 2H+O:P(OH)_3$. A. Italiener measured the solubility of the acid in **water,** and expressing the results in grams of H_3PO_3 and P_2O_3 per 100 grms. of soln.:

	0°	20·25°	25·4°	30°	35°	39·4°
H_3PO_3 . .	75·58	82·00	82·64	84·12	85·00	87·42
P_2O_3 . .	50·7	55·00	55·44	56·43	57·02	58·64

The solubility is thus very great, and in the interval between 0° and 40°, there is no sign of the formation of a definite hydrate. H. Rose observed no development of hydrogen when the phosphites are boiled with **alkali hydroxides.** A. Italiener studied the titration of phosphorous acid with alkali-lye.

H. Wieland and A. Wingler found that **bromine** does not react in dry ethereal soln. with phosphorous acid; but the reaction is rapid if a trace of water be present.

According to O. Ordinaire, when a mol of phosphorous acid is heated with 4 gram-atoms of bromine, there are formed hydrogen bromide and not phosphoric acid, but rather *monobromophosphorous acid* as a deliquescent, crystalline substance, soluble in ether; **chlorine** at 100° acts similarly, producing *monochlorophosphorous acid.* G. Gustavson found that when a mixture of phosphorous acid and bromine is heated in a sealed tube to 100°, phosphoric acid is produced: with 2 gram-atoms of bromine per mol. of phosphorous acid, metaphosphoric acid is formed: $H_3PO_3+Br_2=HPO_3+2HBr$; and with 6 gram-atoms of bromine to 4 mols of the acid, orthophosphoric acid is formed: $4H_3PO_3+3Br_2=PBr_3+3HBr+3H_3PO_4$. W. Manchot and F. Steinhauser observed that bromine in the presence of hydrochloric or sulphuric acid does not oxidize phosphorous acid completely, but in the presence of sodium hydrocarbonate, immediate oxidation occurs, showing that sodium hypobromite is probably the active agent. I. M. Kolthoff found that the oxidation of phosphorous acid by bromine goes very slowly in conc. acid soln., but rapidly when the soln. is buffered to an acidity of $p_{\mathrm{H}}=4$ to 5. A. Sommer discussed the oxidation of phosphorous acid by bromine, obtaining hydrobromic acid as a by-product: $Br_2+H_3PO_3+H_2O=2HBr+H_3PO_4$, G. Gustavson observed similar reactions with **iodine**: with a small proportion of iodine, metaphosphoric acid and phosphorus diiodide are produced; with a mol of the acid and a gram-atom of iodine, some iodine remains unattacked; and with double the proportion of acid: $8H_3PO_3+5I=6H_3PO_4+2HI+PH_4I+PI_2$. According to J. Thomsen, chlorine-water, bromine-water, or iodine-water oxidize the acid to phosphoric acid, and the oxidation is fastest with bromine water. E. Rupp and A. Finck found that soln. of phosphorous acid react only slowly with iodine, but if the liberated hydriodic acid be neutralized by sodium carbonate present in the soln., the oxidation proceeds more quickly. W. Federlin said that the oxidation of phosphorous acid by iodine proceeds very slowly in acidic soln., and is a reaction of the second order. According to B. D. Steele, two reactions of essentially different character occur between iodine and phosphorous acid, one of which preponderates in more strongly acid soln., and the other, in the presence of feeble acids, such as acetic and boric acids. The former of these reactions is catalytically accelerated by the presence of hydrogen ions, and the velocity is proportional to the concentration of phosphorous acid (or of the phosphorous ion) and to the square root of the concentration of the iodine. This is taken to mean that reaction takes place between phosphorous acid mols. (or ions) and iodine atoms, the latter being supplied in extremely small, but sufficient, quantity by the dissociation of the iodine mols. There is a slight apparent retardation of the reaction velocity by the iodine. The second reaction occurs in the presence of salts, such as sodium acetate, bicarbonate, or biborate, and it is very complex; it is accelerated by the presence of phosphorous acid or of sodium acetate, and retarded by the presence of iodine or of potassium iodide. A. D. Mitchell showed that the reaction with iodine and phosphorous acid involves the reversible transformation of two forms of phosphorous acid, the α- or normal form and a β-form: α-$H_3PO_3=\beta$-H_3PO_3; and it involves the I_2-molecule, and the I_3'-ion: α-$H_3PO_3+I_2+H_2O=2HI+H_3PO_4$, and β-$H_3PO_3+I_2+N_2O=H_3PO_4+2H^{\cdot}+I_3'$. The $H^{\cdot}$-ions repress the former, and accelerate the latter, but this acceleration is probably only indirect, and due to the acceleration of the equilibrium between the two forms of the acid, as in the case of hypophosphorous acid. The mechanism of the repressing effect has not been elucidated. The reaction was also studied by E. I. Orloff, A. Brukl and M. Behr, M. Boyer and M. Bauzil, and T. F. Buehrer and O. E. Schupp. C. A. Wurtz found that **hypochlorites** oxidize phosphorous acid to phosphoric acid, and H. Davy observed that **hypochlorous acid** acts in the same way, and that when the acid is warmed with **iodic acid**, iodine and phosphoric acid are formed, but he obtained what he regarded as a compound of phosphorous and iodic acids—*phosphitoiodic acid*—by mixing aq. soln. of the two acids. The yellow product could be sublimed. G. S. Sérullas doubted the existence of this as a chemical individual, although

C. W. Blomstrand made a number of analogous complex acids. D. Vitali found that phosphorous acid reduces **iodates** with the liberation of iodine which is then redissolved as hydriodic acid—the **chlorates** and **bromates** are not reduced by the acid. A. Brukl and M. Behr determined phosphorous acid by determining the iodine liberated by it from phosphorous acid.

F. Wöhler represented the action which occurs when **sulphurous acid** is warmed with phosphorous acid: $3H_3PO_3+H_2SO_3=3H_3PO_4+H_2S$; and the hydrogen sulphide then reacts with the excess of sulphurous acid, forming pentathionic acid and sulphur; and A. Cavazzi symbolized the reaction at 60°–70° by $2H_3PO_3+H_2SO_3=2H_3PO_4+S+H_2O$. C. F. Schönbein mentioned that the product of the reaction quickly decolorizes a soln. of indigo blue; and L. Maquenne said that some hyposulphurous acid is formed at an intermediate stage in the reduction of the sulphurous acid to sulphur. C. A. Wurtz found that hot conc. **sulphuric acid** oxidizes phosphorous to phosphoric acid. According to R. H. Adie, anhydrous phosphorous acid dissolves quietly in conc. sulphuric acid without forming an insoluble compound. The mixture when warmed gives off sulphur dioxide, and contains phosphoric acid only. When anhydrous phosphorous acid was dropped into **sulphur trioxide,** there was a great development of heat, accompanied by the formation of sulphur dioxide and some sulphur. A blue, oily compound separated out in small quantity from the trioxide, which was itself coloured a fine indigo-blue. At the high temp. produced by the reaction, the phosphorous acid reduced some of the trioxide to sulphur, which dissolved in the trioxide to form blue sulphur sesquioxide. The phosphorous acid is almost completely oxidized, by the reduction of the trioxide in the cold, to sulphur dioxide, and, if warm, to sulphur dioxide and sulphur, forming the compound $H_2PO_4,3SO_3$, or $(SO_3H)PO_4$, **sulphonyl phosphate.** W. Federlin found that the reaction between **potassium persulphate** and phosphorous acid is very slow, but in the presence of hydriodic acid, the reaction proceeds with measurable velocity —presumably in two stages: (i) the oxidation of the iodide to iodine by the persulphate, and (ii) the oxidation of the phosphorous acid by the iodine. Iron and copper salts accelerate the reaction. The effect of varying the conc. of the reaction constituents, and the temp. was examined. A. Gutbier found that **selenious acid** is reduced to selenium, and **tellurous acid** to tellurium. H. Davy found that phosphorous acid is oxidized by **nitric acid** to phosphoric acid; A. Joly, that the acid reacts with **metaphosphoric acid,** forming pyrophosphoric acid and hydrogen diphosphide; and L. Amat, that the acid forms hydrogen diphosphide when heated with **phosphorous oxide.** A. Naquet observed that when the acid is heated with **phosphorus trichloride** it forms phosphorous oxide, but K. Kraut represented the reaction: $PCl_3+4H_3PO_3=3H_3PO_4+2P+3HCl$; A. Gautier said that with the crystallized acid and phosphorus trichloride in a sealed tube at 79°, an oxyhydride is formed: $11PCl_3+27H_3PO_3=4P_4HO+11H_4P_2O_7+33HCl$; at 100°, red phosphorus is produced: $3P_4HO+PCl_3+3H_3PO_3=3H_3PO_4+3HCl+13P$; and at 170°, $3PCl_3+7H_3PO_3=4P+3H_4P_2O_7+9HCl$; A. Besson represented the reaction with a conc. soln. of the acid: $PCl_3+H_3PO_3=3HCl+P_2O_3$, and $2P_2O_3=P_2O+P_2O_5$; while A. Geuther said that the reaction is best symbolized: $H_3PO_3+2PCl_3=3P(OH)Cl_2$; $3P(OH)Cl_2=3POCl+3HCl$; $3POCl=P_2O_3+PCl_3$; and $3H_3PO_3+P_2O_3=3H_3PO_4+2P$. He also represented the action of **phosphorus pentachloride**: $H_3PO_3+3PCl_5=PCl_3+3POCl_3+3HCl$—the phosphorus trichloride reacts as just indicated, forming red phosphorus; while the **phosphoryl chloride** reacts: $3POCl_3+2H_3PO_3=3HPO_3+2PCl_3+3HCl$. E. Chambon found that **phosphoryl dichlorobromide** does not produce phosphorus dichlorobromide, but a mixture of phosphorus trichloride and tribromide as well as hydrogen chloride, and metaphosphoric and orthophosphoric acids. B. Grützner found that phosphorous acid reacts with **antimony trioxide,** forming **antimonyl phosphite,** and with **bismuth hydroxide,** forming bismuth phosphite.

T. E. Thorpe and B. North prepared diethyl phosphite, $P(OH)(OC_2H_5)_2$—*vide* *supra.*—by the action of well-cooled phosphorous acid and **alcohol**; the reaction with different alcohols was examined by A. Sachs and N. Levitsky; with **glycerol, glycol,** and **mannite,** by P. Carré; **acetyl chloride,** by N. Menschutkin; **acetic anhydride,** by V. Wedensky; **diazoethane,** by F. C. Palazzo and F. Maggiacomo; etc. According to A. Italiener, it has a slight reducing action on the indicator, *p*-**nitrophenol.**

According to C. F. Rammelsberg, soln. of **copper salts** are decolorized by an excess of phosphorous acid, and cuprous oxide is precipitated; with the copper salt in excess, copper is precipitated: $3H_3PO_3+CuSO_4+3H_2O=3H_3PO_4+H_2SO_4+Cu+2H_2$. According to L. Vanino, if a 10 per cent. aq. soln. of copper sulphate be mixed with phosphorous acid soda-lye produces a turbidity which clears up when more of the alkali-lye is added. M. Major said that the reaction between copper salts and phosphorous acid is completed with the development of hydrogen; and no intermediate stage can be observed in the reduction to the metal. A. Sieverts, and M. Major represented the reaction: $CuSO_4+H_3PO_3+H_2O=Cu+H_3PO_4+H_2SO_4$; they found that cupric chloride yields cuprous chloride. C. A. Wurtz, A. J. Balard, and O. von der Pfordten found that **silver salts** oxidize phosphorous to phosphoric acid with the precipitation of the metal; if the silver salt is in excess, C. F. Rammelsberg represented the reaction: $AgNO_3+H_2O+H_3PO_3=Ag+H+HNO_3+H_3PO_4$. L. Vanino found that silver salts do not behave like copper salts when treated as indicated above. A. Sieverts, and M. Major could detect no intermediate product of the reduction, and no hydrogen was developed; he represented the reaction: $2Ag_3PO_4+3NaH_2PO_3+3H_2O=6Ag+2H_3PO_4+3NaH_2PO_4$. A. Sieverts found that soln. of silver oxide in potassium cyanide soln. are not reduced by phosphorous acid. A. J. Balard, and C. A. Wurtz observed the reduction of **gold salts** to the metal by phosphorous acid; A. Sieverts, and M. Major represented the reaction: $2AuCl_3+3H_3PO_3+3H_2O=2Au+3H_3PO_4+6HCl$. L. Vanino found that with **alkaline earth salts** clear soln. are obtained by the treatment he employed for copper salts—*vide supra.* C. A. Wurtz, and A. J. Balard found that **mercuric salts** are reduced by phosphorous acid to mercury; if an excess of mercuric chloride is used, mercurous chloride is precipitated. C. Montemartini and U. Egidi represented the reaction: $2HgCl_2+H_3PO_3+H_2O=2HgCl+2HCl+H_3PO_4$, and thus considered it to be of the third order, but the velocity constants were not concordant, and they attributed the discrepancy to some unrecognized disturbance; J. B. Garner and co-workers did not succeed in clearing up the difficulty; then G. A. Linhart showed that the reaction is of the first order with respect to mercuric chloride, and the whole reaction possibly occurs in two stages: $HgCl_2+H_3PO_3=HCl+HgCl+H_2PO_3$, followed by $2H_2PO_3+H_2O=H_3PO_4+H_3PO_3$. The latter reaction is much more rapid than the former. The reaction is accelerated by acids. The reaction was also studied by A. Linhart and E. Q. Adams, N. R. Dhar, W. Federlin, and B. D. Steele. According to A. D. Mitchell, there is first a reversible reaction between the ordinary α-form of phosphorous acid and a β-form: $\alpha\text{-}H_3PO_3 \rightleftharpoons \beta\text{-}H_3PO_3$, which is accelerated in both directions by $H^{\cdot}$-ions and $\beta\text{-}H_3PO_3+HgCl_2+H_2O=Hg+H_3PO_4+2HCl$, followed by the instantaneous reaction $Hg+HgCl_2=Hg_2Cl_2$. In the absence of extraneous Cl'-ions initially, the reaction $HgCl'+\alpha\text{-}H_3PO_3+H_2O=H_3PO_4+Hg+2H^{\cdot}+Cl'$ preponderates until the accumulation of Cl'-ions reduces it to a lower order of magnitude. With low conc. of $H^{\cdot}$-ions (*i.e.* in the presence of an excess of sodium acetate) another instantaneous reaction occurs; and yet another, $HgCl_2+\alpha\text{-}H_3PO_3 \rightleftharpoons X+H^{\cdot}+Cl'$, where X represents an intermediate compound. The resultant reaction is therefore compounded of a side and consecutive reactions. The reaction was also studied by R. M. Purkayostha and N. R. Dhar. B. Grützner observed that colloidal **alumina** forms a basic phosphite when treated with phosphorous acid; and that **chromic salts** are not reduced to an appreciable extent by phosphorous acid, and chromic hydroxide dissolves in the acid. N. R. Dhar found the reaction to be unimolecular with respect to chromic acid when an excess of phosphorous acid is present. C. A. Wurtz, and A. J. Balard found that **chromates** are quickly reduced by phosphorous acid; W. Gibbs found that phosphorous acid forms complex salts with **molybdenum trioxide**, and with **tungsten trioxide**. A. J. Balard, and C. A. Wurtz found that phosphorous acid reduces the **permanganates**. L. Amat found the speed of the reduction proceeds more quickly the more conc. the soln., the more acidic the liquid, and the higher the temp. The reaction is incomplete at ordinary temp. O. Kühling represented the reaction: $3H_3PO_3+2KMnO_4=3H_3PO_4+2MnO_2+K_2O$; and J. Pinsker studied the reaction. According to L. Vanino, **ferrous and ferric salts**, like copper salts, form clear soln. when treated as indicated above. B. Grützner found that freshly precipitated ferric hydroxide forms ferric phosphite when treated with phosphorous acid. M. Major found that at 50°, **nickel** is dissolved by phosphorous acid. A. Sieverts found that **cobalt salts** and **nickel salts** are not reduced by phosphorous acid; B. Grützner showed that cobalt and nickel hydroxides dissolve in the acid without reduction; and L. Vanino, that soln. of cobalt and nickel sulphates behave like those of copper sulphate—*vide supra*. A. Sieverts found that **palladium salts** are reduced in the cold by phosphorous acid.

§ 18. The Phosphites

C. A. Wurtz [1] said that the affinity of phosphorous acid for the bases is small, but they have a great tendency to form double salts. Phosphorous acid unites with bases and metal-oxides, forming **phosphites.** There are two types of salts—*primary phosphites*, MH_2PO_3; and *secondary phosphites*, M_2HPO_3, where M denotes a monad. C. Zimmerman reported a *tertiary phosphite*, Na_3PO_3, but, according to L. Amat, C. Zimmermann mistook normal sodium phosphite, Na_2HPO_3, for the tertiary salt. The alkali and calcium phosphites are soluble in water, the other salts are but sparingly soluble. Many of the less soluble phosphites are soluble in an excess of the acid, probably owing to the formation of soluble double salts. The phosphites have been specially studied by C. A. Wurtz, H. Rose, C. F. Rammelsberg, L. Amat, J. L. Gay Lussac, etc. The double phosphites are soluble in water. The phosphites—solid or in aq. soln.—are fairly stable in air at ordinary temp., but, when heated, they decompose with the evolution of hydrogen or phosphine, and the formation of ortho- or pyro-phosphate—*e.g.* $5PbHPO_3 = Pb_2P_2O_7 + Pb_3(PO_4)_2 + PH_3 + H_2$. Boiling the phosphite with alkali-lye furnishes hydrogen: $Na_2HPO_3 + NaOH = Na_3PO_4 + H_2$, but with dil. soln. no appreciable amount of hydrogen is evolved.

A. F. de Fourcroy and L. N. Vauquelin,[2] and H. Rose prepared **ammonium phosphite,** $(NH_4)_2HPO_3.H_2O$, by saturating an aq. soln. of phosphorous acid with ammonia, and evaporating the soln. to a syrupy consistence when it yields large "four-sided prisms with quadrilateral summits." C. A. Wurtz evaporated the soln. over conc. sulphuric acid, and analyzed the product. G. Lemoine obtained the salt as a by-product in the action of ammonium sulphide on phosphorus sesquisulphide. The salt is very deliquescent. When the salt is kept in vacuo, or when the soln. is evaporated at 100°, C. A. Wurtz found that it lost its water of crystallization along with some ammonia; and H. Rose, and A. F. de Fourcroy and L. N. Vauquelin reported that when the salt is heated it loses ammonia, leaving hydrated phosphorous acid as a residue, which is decomposed at a higher temp. into phosphine and phosphoric acid. L. Amat found that when kept for 24 hrs. in vacuo, the monohydrate becomes anhydrous: $(NH_4)_2HPO_3.H_2O = (NH_4)_2HPO_3 + H_2O$. The anhydrous salt was also made by L. Amat by passing ammonia over the hydrophosphite at 100°; and T. E. Thorpe and A. E. H. Tutton obtained it as a by-product along with diamidophosphorous acid, when ammonia acts on phosphorous acid. According to L. Amat, the white powder has a dissociation press. of 15 mm. at 75°. H. Stamm found that the salt is precipitated from its conc. aq. soln. by ammonia. L. Amat, and A. P. Sabanéeff made **ammonium hydrophosphite,** $(NH_4)H(HPO_3)$, by neutralizing a soln. of phosphorous acid with ammonia, using methyl-orange as indicator. The soln. is evaporated until a drop crystallizes when cooled. The evaporation must be carefully performed or the salt will decompose. It is also formed when normal ammonium phosphite is heated to 100°, or kept in vacuo. A. P. Sabanéeff said that the salt is isomeric with hydroxylamine hypophosphite. According to H. Dufet, the crystals are monoclinic prisms with the axial ratios $a:b:c = 0{\cdot}7616:1:0{\cdot}9618$, and $\beta = 103° \, 6\frac{3}{4}'$; the optic axial angle $2H_a = 13° \, 50'$. L. Amat said that the salt is stable at 100°, but melts at 123°; while A. Sabanéeff said that it melts with partial decomposition at 120°, and that the presence of a trace of water lowers the m.p. According to L. Amat, the molten salt begins to decompose at 145° with the loss of ammonia, but not phosphine; when heated still more, phosphine is also given off, and phosphorous acid remains. The salt is very soluble in water, since 100 grms. of water dissolve 171 grms. of salt at 0°; 190 grms. at 14·5°; and 260 grms. at 31°. Very little ammonia is absorbed by the salt at ordinary temp., but at 100°, ammonia is freely absorbed, forming the normal phosphite. A. P. Sabanéeff said that the salt does not reduce alkaline copper salts in the cold, but it gives a precipitate with barium chloride. J. Zawidzky studied the rate of the isomeric change of the alkyl phosphites.

According to K. A. Hofmann and V. Kohlschütter, **ammonium hydroxylamine phosphite,** $(NH_4)(NH_3OH)(HPO_3)$, is obtained by neutralizing phosphorous acid with ammonia, then adding four times the quantity of ammonia and two mol. proportions of hydroxylamine hydrochloride to one of the acid; after remaining one hour, the soln. is precipitated with alcohol and the product recrystallized from absolute alcohol. It is also obtained by heating normal ammonium phosphite with a soln. of hydroxylamine hydrochloride in absolute ethyl alcohol and dissolving out the excess of hydroxylamine hydrochloride from the product by warming it with methyl alcohol. It crystallizes in slender, white needles, and at once reduces Fehling's soln. and ammoniacal silver nitrate. A. P. Sabanéeff said that this salt is isomeric with ammonium hydrophosphate. K. A. Hofmann and V. Kohlschütter made **hydroxylamine phosphite,** $(NH_3OH)_2(HPO_3)$, by mixing an aq. soln. of disodium phosphite with 3 mol. proportions of hydroxylamine hydrochloride, and after crystallizing out the sodium chloride by evaporation in vacuo over sulphuric acid, the gummy residue is crystallized from absolute alcohol; it crystallizes in long, colourless needles, burns, when heated, with a green flame and evolution of hydrogen phosphide, and quickly reduces Fehling's soln. and ammoniacal silver nitrate. A. P. Sabanéeff said that **hydroxylamine hydrophosphite,** $(NH_3OH)H(HPO_3)$, is isomeric with ammonium dihydrophosphate. He obtained normal **hydrazine phosphite,** $(N_2H_6)(HPO_3)$, from barium phosphite and hydrazine sulphate; it is very hygroscopic, and melts at 36°. It is isomeric with ammonium hydrogen amidophosphate, which decomposes at 120° and melts at 305°. He also made **hydrazine hydrophosphite,** $H(HPO_3)_2N_2H_6(H.HPO_3)_2$, obtained from hydrazine sulphate and barium hydrogen phosphite, melting at 82° without decomposition. It is isomeric with ammonium hypophosphate, $(NH_3)_2H_4P_2O_6$, which melts at 170°.

A. Rosenheim and W. Reglin[3] prepared **lithium hydrophosphite,** $Li_2HPO_3.H_2O$, in 4-sided plates, from a soln. of equimolar parts of lithium carbonate and phosphorous acid concentrated for crystallization on a water-bath. The salt has a negative temp. coeff. for the solubility, S grms. of $Li_2HPO_3.H_2O$, in 100 grms. of soln.:

	0°	25°	30°	35°	40°	45°	50°	61°	98°
S .	9·07	7·47	7·07	6·82	6·64	6·29	6·09	5·75	4·24

the solid phase was always the monohydrate. The $H^{\cdot}$-ion conc. of a N-soln. at 20° is $p_H=8{\cdot}14$, or $[H^{\cdot}]=7{\cdot}34\times10^{-9}$ grms. per litre. The lowerings of the f.p. with 0·4014, 0·9095, and 1·4076 grm. of the monohydrate in respectively 19·243, 19·33, and 19·41 grms. of water were 0·820°, 1·7550°, and 2·710°, respectively corresponding with the factors $i=2{\cdot}37$, 2·25, and 2·25, thus showing that the salt is probably associated to $(Li_2HPO_3)_2$ in soln. The eq. electrical conductivities, λ, for a mol of the salt in v litres of water at 25°:

v . . .	32	64	128	256	512	1024
λ . . .	68·1	72·6	76·4	82·1	86·0	102·4

There is no evidence of adsorption when the salt is crystallized from a conc. soln. of lithium hydroxide. L. Amat obtained easily soluble **lithium dihydrophosphite,** LiH_2PO_3—from a soln. of lithium carbonate or hydroxide neutralized with phosphorous acid, using methyl-orange as indicator. C. Zimmermann's report of the preparation of **sodium orthophosphite,** Na_3PO_3, has already been described. P. L. Dulong, H. Dufet, and C. A. Wurtz prepared **sodium hydrophosphite,** $Na_2HPO_3.5H_2O$, by neutralizing a soln. of phosphorous acid with sodium carbonate, and evaporating the liquid for crystallization. A. Italiener recommended using α-naphtolphthalein as indicator, and evaporated the syrupy liquid over conc. sulphuric acid. The analysis of the long, acicular crystals so obtained corresponded closer with $Na_2HPO_3.5{\cdot}5H_2O$, than with the pentahydrate. A. F. de Fourcroy and L. N. Vauquelin appear to have obtained this salt from the so-called *acide phosphatique*—*vide supra.* P. L. Dulong said that the crystals are rhombohedra inclined to the cubical form ; and H. Dufet gave for the axial ratios of the rhombic bipyramidal crystals $a:b:c=0{\cdot}6998:1:0{\cdot}7813$. The index of refraction for Na-light is $\beta=1{\cdot}4434$; the birefringence is positive and feeble ; the optic axial angle $2V=43°\ 16'$ for Li-light ; 44° 7′ for Na-light ; and 44° 45′ for Tl-light, and there is a rise of about 10′ for a degree rise of temp. H. Rose said that the crystals decompose when heated, giving off hydrogen. L. Amat gave 53° for the m.p. ; and the salt is dehydrated at 150°. The anhydrous salt is formed by keeping the pentahydrate in vacuo, or over conc. sulphuric acid, or else heating it to 120°. K. Kraut said that when heated in a current of air, a little phosphine is given off at 200°–250°, and when the residue is digested in water, a little red phosphorus remains undissolved. F. M. Raoult said that the f.p. is lowered 0·327° by the dissolution of a gram of the anhydrous salt in 100 c.c. of water ; and the mol. lowering of the f.p. is 41·2°. J. Thomsen measured the heat of neutralization of phosphorous acid and sodium hydroxide—*vide supra.* L. Amat gave for the heat of formation $H_3PO_3+2NaOH=Na_2HPO_3+2H_2O_{solid}+41{\cdot}6$ Cals. and for the heat of soln., 4·6 Cals. at 13·5°. A. Italiener, and I. Müller gave 10° for the hydrogen-ion conc. The solubility of the salt in water is greater than that of phosphorous acid ; expressing the results in grams of $Na_2(HPO_3)$ per 100 grms. of soln., A. Italiener found :

	0°	20°	25·2°	29·9°	38°	42·7°
Solubility .	80·72	81·16	82·21	84·96	91·44	93·68

The curve shown in Fig. 35 is not inconsistent with the existence of another hydrate with a transition point near 20°, but none was found. E. Blanc estimated that in 0·0075*N*-soln., 0·021 per cent. of sodium phosphite is hydrolyzed. A. Italiener gave for the H-ion conc. [H$^{\cdot}$] 10^{-9} grm. per litre at 20°. H. Stamm found that the salt is precipitated by ammonia from its conc. aq. soln. P. L. Dulong, H. Rose, and C. A. Wurtz prepared **potassium phosphite,** $K_2(HPO_3)$, by neutralizing phosphorous acid with potassium hydroxide. H. Rose found the syrupy liquid crystallized when kept in vacuo. C. A. Wurtz said the salt can be dried at 280° without decomposition. P. L. Dulong said that the salt is deliquescent in air, and insoluble in alcohol. According to A. Gutmann, a cold or boiling soln. of sodium thiosulphate does not act on sodium or potassium phosphite—*vide* the arsenites. N. N. Mittra and N. R. Dhar found that the reaction with mercuric chloride and sodium phosphite as primary reactions is hastened by the simultaneous reaction of mercuric chloride with sodium arsenite or arsenious acid.

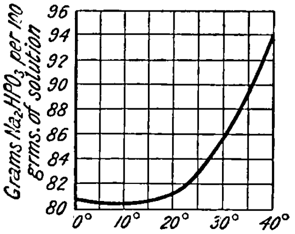

FIG. 35.—The Solubility of Sodium Phosphite in Water.

L. Amat prepared **lithium dihydrophosphite,** $LiH(HPO_3)$, by neutralizing phosphorous acid with lithium carbonate or hydroxide, using methyl orange as indicator, and evaporating to a syrup. The syrupy liquid is crystallized by allowing it to stand in vacuo. The salt is very soluble in water. L. Amat prepared **sodium dihydrophosphite,** $NaH(HPO_3).2\frac{1}{2}H_2O$, by neutralizing a soln. of phosphorous acid with sodium hydroxide or carbonate, and seeding the conc. soln. with a crystal of the salt previously prepared. The soln. is very prone to undercooling. A. Italiener obtained the soln. in a similar manner, and said that the syrupy liquid must stand in an ice-chest over phosphorus pentoxide for some time to crystallize.

L. Amat said that crystallization occurs when the aq. soln. is cooled to —23° ; and he obtained a soln. of the salt by the action of phosphorus trichloride on soda-lye—but the yield was poor. The salt loses all its water of crystallization in vacuo, or over conc. sulphuric acid ; while A. Italiener said that it is the anhydrous salt itself which crystallizes from the aq. soln. H. Dufet found that the salt prepared by L. Amat occurs in monoclinic prisms, with the axial ratios $a : b : c = 1{\cdot}2017 : 1 : 0{\cdot}7964$, and $\beta = 109° 53'$. The optical axial angle $2V = 77° 46'$ for Na-light, $77° 36\frac{1}{2}'$ for Li-light, and $77° 40'$ for Tl-light. The indices of refraction are $\alpha = 1{\cdot}4193$, $\beta = 1{\cdot}4309$, and $\gamma = 1{\cdot}4493$ for Na-light, while β for Li-light is 1·4281, and for Tl-light, 1·4334. The birefringence is positive. L. Amat gave 42° for the m.p. F. M. Raoult gave 0·307° for the lowering of the f.p. when one gram of the anhydrous salt is dissolved in 100 grms. of water ; and the mol. lowering of the f.p. is therefore 32·0. L. Amat gave for the heat of formation at 15°, $H_3PO_3 + NaOH = NaH_2PO_3 + H_2O_{solid} + 25{\cdot}2$ Cals. ; for the heat of hydration, $NaH_2PO_{3solid} + 2{\cdot}5H_2O_{solid} = NaH_2PO_3.2\frac{1}{2}H_2O. + 9{\cdot}65$ Cals. L. Amat gave for the heat of soln. of the anhydrous salt, 0·75 Cal. at 13°, and of the hemipentahydrate, —5·3 at 15°. J. Thomsen's observations on the heat of neutralization of phosphorous acid have been previously discussed. A. Italiener, and I. Müller gave $6{\cdot}887 \times 10^{-5}$ for the hydrogen-ion conc. A. Italiener found the tendency of the salt to form undercooled soln. so great that it was difficult to measure the solubility ; L. Amat found 100 grms. of water at 0° dissolved 56 grms. of salt ; 66 grms. at 10° ; and 193 grms. at the m.p. L. Amat obtained **potassium dihydrophosphite,** $KH(HPO_3)$, by a process like that used for the sodium salt. The crystals retain some adsorbed water which is lost in vacuo at 100°. H. Dufet found that the crystals are monoclinic prisms with the axial ratios $a : b : c = 1{\cdot}3913 : 1 : 1{\cdot}7197$, and $\beta = 101° 49\frac{1}{2}'$. The optical axial angle $2V = 36° 14'$; and the index of refraction $\beta = 1{\cdot}45$. L. Amat found that 100 grms. of water at 10° dissolve 172 grms. of the salt.

C. A. Wurtz reported **sodium heptahydrotriphosphite,** $Na_2HPO_3.2H_3PO_3.\frac{1}{2}H_2O$, or $Na_2H_4(HPO_3)_3.\frac{1}{2}H_2O$, in prismatic crystals, by evaporating in vacuo a soln. of phosphorous acid one-third neutralized with sodium hydroxide. The salt is deliquescent in moist air ; it loses its water of crystallization at 200° ; and at 245°, the evolution of phosphine begins. C. A. Wurtz obtained **potassium heptahydrotriphosphite,** $K_2H_4(HPO_3)_3$, or $K_2HPO_3.2H_3PO_3$, by evaporating in vacuo the soln. obtained by one-third neutralizing phosphorous acid. The crystals melt without appreciable loss at 200°, but at 250°, begin to emit phosphine.

H. Rose noted that when ammonium phosphite is added to a soln. of cupric chloride, the flocculent precipitate is not decomposed by washing. C. A. Wurtz obtained a granular, crystalline precipitate of **copper phosphite,** $Cu(HPO_3).2H_2O$, by treating a soln. of cupric acetate with phosphorous acid ; and L. Amat evaporated in vacuo a soln. of copper carbonate in phosphorous acid, and obtained a gum-like or a crystalline mass. The blue crystals lose 25 per cent. of water when kept over sulphuric acid ; and they are partially decomposed at 120°. C. F. Rammelsberg said the salt can be boiled in water without decomposition, but, according to H. Rose, the salt is reduced by boiling with phosphoric acid ; and L. Amat was unable to prepare the acid-salt because of this reduction. H. Rose found that when heated in a retort much water and hydrogen, but not phosphine, are given off, and a mixture of copper and normal copper phosphate remains. R. Kremann showed that when a soln. of sodium phosphite containing some copper salt is electrolyzed, some copper migrates to the anode, and he therefore assumes that a *hydrophosphitocupric acid* is present in the soln. $H(CuPO_3)$, or rather a *sodium cupric phosphite*, $Na[CuPO_3]$. A. Rosenheim and co-workers could not prepare complex cupric phosphites. In spite of the reducing action of phosphites on silver salts—*vide supra*—A. Sänger was able to make **silver phosphite,** Ag_2HPO_3, as a white crystalline precipitate, by adding silver nitrate to a soln. of phosphorous acid. The salt quickly turns brown, and ultimately forms a black powder. No *gold phosphite* has been reported.

H. Rose obtained a white precipitate of **calcium phosphite,** $CaHPO_3.2H_2O$, by mixing soln. of ammonium phosphite and calcium chloride ; and C. A. Wurtz, by neutralizing a soln. of phosphorous acid with ammonia, and then adding calcium chloride—rejecting the first fraction precipitated. C. F. Rammelsberg obtained calcium phosphite by mixing an aq. soln. of phosphorus trichloride with calcium chloride, and adding ammonia. P. L. Dulong found that the salt crystallizes by the slow evaporation of its aq. soln. C. A. Wurtz found that the water of crystallization is lost at 205° ; and C. F. Rammelsberg, at 200°–300°. At a red-heat hydrogen is given off, and calcium pyrophosphate is formed along with some phosphorus which colours the residue yellowish-brown. R. Rother said that when heated in a tube, phosphine is given off with a feeble detonation, and that at a certain temp., the mass suddenly becomes incandescent. P. L. Dulong found that the salt is hydrolyzed by boiling water with the precipitation of a basic phosphite, and the dissolution of an acid salt. H. Rose, and C. F. Rammelsberg prepared **strontium phosphite,** $Sr(HPO_3).1\frac{1}{2}H_2O$, by methods analogous to those employed for the calcium salt. P. L. Dulong said that the salt is sparingly soluble in water, and the soln. crystallizes when allowed to evaporate spontaneously. P. L. Dulong obtained crystals by the slow evaporation of its aq. soln. The crystalline precipitate was found by C. F. Rammelsberg to lose its water of crystallization at 200°–250°, and the loss of the last mol of water is attended by a partial decomposition of the salt whereby hydrogen and a little phosphine is given off. The residue contains strontium pyrophosphate mixed with a little red phosphorus. P. L. Dulong found that the salt is hydrolyzed in a boiling aq. soln., forming an insoluble basic salt, and a soluble acid salt.

J. J. Berzelius made normal **barium phosphite,** $BaHPO_3$, by mixing soln. of ammonium phosphite and barium chloride ; after the soln. has been allowed to stand for some time, a white crystalline crust of the phosphite appears on the liquid. C. F. Rammelsberg obtained the solid salt as a precipitate by adding ammonia to a soln. of the acid phosphite. A. Italiener prepared an aq. soln. of the salt by mixing soln. of sodium phosphite and barium chloride. The conditions of equilibrium in the presence of soln. of phosphorous acid are indicated in Fig. 36. P. L. Dulong found that an aq. soln. of the salt yields crystals on evaporation. The salt was analyzed by J. J. Berzelius, H. Rose, C. Zimmermann, and C. A. Wurtz, who reported the salt to be anhydrous $BaHPO_3$; but, according to A. Italiener, the salt is hemihydrated, $BaHPO_3.\frac{1}{2}H_2O$. C. F. Rammelsberg observed very little loss in weight—1·71 per cent.—at 200°–250° ; but when heated to redness, C. F. Rammelsberg, in agreement with H. Rose, observed that hydrogen and water are given off while the pyrophosphate, accompanied by a little phosphorus, remains. When the salt is evaporated with nitric acid, J. J. Berzelius found that the pyrophosphate is produced, while C. F. Rammelsberg obtained barium metaphosphate and nitrate as well. P. L. Dulong found that the salt is only sparingly soluble in water. A. Italiener showed that 100 grms. of soln. contained 0·6270 grm. of $BaHPO_3$ at 30°, and the result at 65° was very little different. P. L. Dulong observed that the salt is hydrolyzed by boiling water, forming an insoluble basic salt, and a soluble acid salt. H. W. F. Wackenroder found that barium phosphite is soluble in an aq. soln. of ammonium chloride.

Three acidic salts of barium phosphite have been reported with $BaHPO_3 : H_3PO_3$ as 2 : 1, 1 : 1, and 2 : 3. A. Italiener examined the ternary system $BaO–P_2O_3–H_2O$ at 30°. The following is a selection from the results, where the numerical data refer to the number of grams of the given component present in 100 grms. of soln. :

BaO .	4·22	4·70	4·76	9·90	26·91	27·77	8·42	25·77
P_2O_4 .	1·41	3·38	3·70	4·17	9·22	9·26	18·56	36·34
	$BaHPO_3.\frac{1}{2}H_2O$		$Ba_2(H_2PO_3)_3 5H_2O$			$Ba(H_2PO_3)_2$		H_3PO_3

The results are plotted in Fig. 36. C. F. Rammelsberg reported **barium dihydrotriphosphite,** $2BaHPO_3.H_3PO_3.8H_2O$, *i.e.* $Ba_2H_2(HPO_3)_3.8H_2O$, to crystallize from a soln. of the normal phosphite in warm phosphorous acid. This appears to be the salt represented by A. Italiener as a pentahydrate. The conditions of equilibrium are indicated in Fig. 36; similar remarks apply to **barium dihydrodiphosphite,** $BaH_2(HPO_3)$. H. Rose said that the *hemihydrate* is formed when the normal phosphite is digested with not too large an excess of phosphorous acid, and evaporating the filtrate in vacuo. It intumesces when heated, and gives off a mixture of phosphine and hydrogen, and, according to C. F. Rammelsberg, leaves behind a mixture of the metaphosphate and pyrophosphate. C. A. Wurtz reported the *monohydrate* to be formed from a soln. of the normal phosphite in sulphuric acid, or of barium hydroxide in phosphorous acid. C. F. Rammelsberg by a similar process alleged that the *dihydrate* is formed; and L. Amat, the *trihydrate.* A. Italiener did not find one of these four hydrates in her study of the ternary system, Fig. 36; and a similar remark applies to C. F. Rammelsberg's **barium hexahydropentaphosphite,** $2BaHPO_3.3H_3PO_3.2H_2O$, or $Ba_2H_6(HPO_3)_5.2H_2O$, said to be obtained in acicular crystals by spontaneously evaporating a soln. of the normal phosphite in the calculated quantity of phosphorous acid.

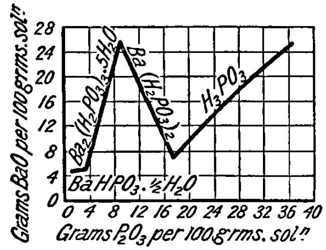

FIG. 36.—Solid Phases in the Ternary System: $BaO–P_2O_3–H_2O$.

H. Rose obtained **beryllium phosphite** as a white precipitate from soln. of ammonium phosphite and beryllium chloride. When heated in a retort, it becomes incandescent, giving off hydrogen but no phosphine. B. Bleyer and B. Müller could obtain only the feebly basic salt **beryllium oxytetraphosphite,** $4BeHPO_3.BeO.7H_2O$, as a white amorphous powder, from soln. of ammonium phosphite and beryllium sulphate. When heated, self-accendible phosphine is evolved, and beryllium pyrophosphate remains. H. Rose also made **magnesium phosphite,** $MgHPO_3.6H_2O$, by evaporating in vacuo the filtrate from a boiling soln. of magnesia is very dil. phosphorous acid. C. F. Rammelsberg obtained it from a soln. of magnesium carbonate in phosphorous acid; and the hemipentahydrate from a soln. of phosphorus trichloride and magnesium sulphate. The formula just indicated is based on the analysis of C. F. Rammelsberg. H. Rose found that at a red-heat much water is evolved, and then a mixture of hydrogen and phosphine, leaving a residue of the pyrophosphate coloured with red phosphorus. C. F. Rammelsberg added that the residue also contains some magnesia. When digested with nitric acid, magnesium pyrophosphate is formed. H. Rose said that the salt is sparingly soluble in water, and more soluble in cold than in hot water. L. Amat prepared the acidic salt, **magnesium dihydrodiphosphate,** $MgH_2(HPO_3)_2$, analogous to the corresponding salts of the three alkaline earths. H. Rose prepared **zinc phosphite,** $ZnHPO_3.2\frac{1}{2}H_2O$, by treating an aq. soln. of phosphorus trichloride, neutralized with ammonia, with zinc sulphate; part of the salt separates in the cold, and part on boiling, since the salt is more soluble in cold than it is in hot water. By treating an alkali phosphite soln. with zinc sulphate, A. Rosenheim, S. Frommer and W. Händler obtained the salt $3ZnHPO_3.8H_2O$. C. F. Rammelsberg used a modification of H. Rose's process and found that the salt loses its water of crystallization at 280°, and at a red-heat gives off hydrogen and only a trace, if any, of phosphine. There remains a mixture of zinc phosphide and pyrophosphate. If the aq. soln. be evaporated spontaneously in air, it furnishes the anhydrous phosphite. C. F. Rammelsberg evaporated soln. of the normal phosphite in phosphorous acid of different conc. and obtained acidic salts, **zinc hydrophosphites,** represented by $Zn_2H_3P_3O_8.2H_2O$; $Zn_3H_5P_5O_{13}.3H_2O$; and $Zn_2H_9P_5O_{14}.H_2O$. Neither the conditions of equilibrium nor the individuality of these products has been established. C. F. Rammelsberg obtained **cadmium phosphite,** $CdHPO_3$, as a white powder, from mixed soln. of cadmium sulphate and sodium or ammonium phosphite. A. Rosenheim, S. Frommer and W. Händler treated a soln. of cadmium sulphate with alkali phosphite, and obtained the salt, $3CdHPO_3.5H_2O$; they could not make complex cadmium phosphites. According to C. F. Rammelsberg, when the phosphite is heated, hydrogen almost free from phosphine is given off, some cadmium sublimes, and there remains a mixture of cadmium and its phosphide and pyrophosphate. H. Rose obtained **mercuric phosphite** as a white powder on adding phosphorous acid to a soln. of mercuric nitrate; the product decomposes with the separation of mercury as soon as it is warmed.

H. Rose neutralized an aq. soln. of phosphorus trichloride with ammonia, and added a soln. of alum in excess, when **aluminium phosphite** was formed as a white powder which gave off a mixture of hydrogen and phosphine when heated to redness. B. Grützner obtained **aluminium hydroxyphosphite,** $2Al(OH)_3.Al_2(HPO_3)_3$, by adding phosphorous acid to a slurry of colloidal alumina and water. If the clear soln. is boiled, a precipitate is obtained which when heated gives off phosphine. The analysis corresponds with the formula just indicated. L. Amat obtained well-defined crystals of **thallous hydrophosphite,** $TlH(HPO_3)$, by neutralizing a soln. of phosphorous acid with thallous carbonate. The salt melts at 70°–71°, and is very soluble in water. In summer it attracts moisture from the atm., and becomes liquid; in winter, it becomes solid again. It is neutral towards methyl-orange.

H. Rose neutralized an aq. soln. of phosphorus trichloride, with ammonia, and added an aq. soln. of titanium tetrachloride, the resulting white precipitate contained some **titanium phosphite.** When heated, it gave a mixture of hydrogen and phosphine; and left a black residue of reduced titanic oxide—not the monoxide. O. Kauffmann added phosphorous acid to a soln. of thorium nitrate, and warmed the mixture on a water-bath. The white product was **thorium phosphite,** $Th(HPO_3)_2.3H_2O$. It gradually oxidized at 105°; it was insoluble in water and in dil. acids and alkali-lye; but dissolved slowly in mineral acids, particularly when warmed. If soln. of sodium hydrophosphite and thorium nitrate be mixed as before, the octohydrate, $Th(HPO_3)_2.8H_2O$, is formed.

H. Rose obtained **stannous phosphite,** $Sn(HPO_3)$, by treating a soln. of stannous chloride with ammonium phosphite and washing the white precipitate until the wash-water, boiled with nitric acid, gives no precipitate with silver nitrate. The salt blackens when heated, gives off hydrogen and phosphine, and a sublimate of phosphorus. It is gelatinized by heating with nitric acid, forming stannic phosphate. The soln. of the salt reduces many other metal salts. A. Rosenheim and co-workers obtained a similar product; but they could not obtain complex salts. H. Rose also obtained a white precipitate—possibly **stannic phosphite**—by the action of ammonium phosphite on stannic chloride. It develops water when heated, and the stannic oxide passes into stannous oxide. Normal **lead phosphite,** $Pb(HPO_3)$, was made by H. Rose, and J. J. Berzelius, by treating a soln. of lead acetate with ammonium phosphite; by L. Amat using lead nitrate and phosphorous acid or one of the sodium phosphites, or lead oxide and phosphorous acid, or by treating lead acid phosphite, pyrophosphite, or nitratophosphite with water; and by C. F. Rammelsberg, by neutralizing phosphorous acid with lead carbonate. The product retains about 2·7 per cent. of water. A. Rosenheim and co-workers obtained a similar product. According to H. Rose, and C. F. Rammelsberg, when lead phosphite is heated it develops hydrogen and phosphine, along with a sublimate of phosphorus, and leaves a residue of lead phosphide and pyrophosphate. According to V. Ipatieff, lead phosphite is converted into lead and phosphoric acid when heated in hydrogen. J. J. Berzelius said that the phosphite can be dissolved in cold nitric acid without decomposition, but when heated it forms the pyrophosphate. R. Weinland and F. Paul prepared **lead tetrabromophosphite,** $2PbBr_2.PbHPO_3.H_2O$; and **lead dichlorophosphite,** $PbCl_2.PbHPO_3.H_2O$. L. Amat prepared **lead dinitrato-phosphite,** $Pb_2(NO_3)_2(HPO_3)$, by adding an excess of lead nitrate to a cold soln. of sodium hydrophosphite; or sodium pyrophosphite; or by treating normal lead phosphite with a soln. of lead acetate in dil. nitric acid; or by treating lead phosphite with dil. nitric acid. The salt is stable in air, and at temp. up to 110°. If strongly heated, it explodes. Water decomposes it into lead nitrate and phosphite—

particularly if the water is boiling. If it is heated with nitric acid and calcined it forms a mixture of lead oxide and phosphate. C. A. Wurtz found that lead phosphite is reduced by warm sulphuric acid to sulphur dioxide; and H. Rose, that it is soluble in phosphorous acid, and the soln., according to C. A. Wurtz, gives white flocks with ammonia. When the normal phosphite is digested for some weeks with aq. ammonia, and the product washed with alcohol, H. Rose found that **lead dioxydiphosphite,** $4PbO.P_2O_3.2H_2O$, or $2PbO.2Pb(HPO_3).H_2O$, is formed; and C. A. Wurtz reported **lead oxydiphosphite,** $PbO.2Pb(HPO_3)$. L. Amat found that the soln. of the normal phosphite in phosphorous acid yields **lead dihydrodiphosphite,** $PbH_2(HPO_3)_2$, which can be washed with absolute ether and dried in vacuo or at 100°. The colourless crystals form the pyrophosphite at 100°; water forms normal lead phosphite and phosphorous acid. A. Rosenheim and co-workers could not prepare complex salts.

H. Rose prepared **antimonyl phosphite,** $(SbO)H_2PO_3$, by neutralizing an aq. soln. of phosphorus trichloride with ammonia, and adding tartar emetic; the white precipitate gives off hydrogen when heated, and it is soluble in hydrochloric acid. B. Grützner treated antimony oxide with a soln. of phosphorous acid, and obtained microscopic needles of the above composition. No salt could be prepared from antimony oxide, and potassium hydrophosphite. B. Grützner also prepared **bismuth phosphite,** $Bi_2(HPO_3)_3.3H_2O$, by the action of phosphorous acid on bismuth oxide; and L. Vanino and F. Hartl, by adding phosphorous acid to a soln. of bismuth nitrate and mannite. H. Rose obtained the salt by neutralizing an aq. soln. of phosphorus trichloride with ammonia, and adding a soln. of bismuth chloride as nearly neutral as possible. The small, four-sided, acicular crystals are almost insoluble in water; they lose their water of crystallization at 105°; and when heated give off hydrogen alone. L. Vanino and F. Hartl said the salt is not decomposed by potash-lye; it reacts slowly with potassium iodide; and rapidly with hydrogen sulphide.

H. Rose treated an aq. soln. of chromic chloride with a soln. of phosphorus trichloride, and obtained **chromium phosphite,** partly as a green soln., and partly as a precipitate. The phosphite appears as a voluminous, green powder, which when heated gives off hydrogen but no phosphine. A. Rosenheim and S. Frommer prepared a series of salts, $R[Cr(HPO_3)_2].nH_2O$, by the action of a conc. soln. of chromium chloride on an aq. soln. of an alkali phosphite, *e.g.* **ammonium chromium phosphite,** $NH_4[Cr(HPO_3)_2].8H_2O$; **potassium chromium phosphite,** $K[Cr(HPO_3)_2].12H_2O$; **sodium chromium phosphite,** $Na[Cr(HPO_3)_2].14H_2O$, as well as a guanidinium salt. A. Italiener also reported complex $K[Cr(HPO_3)_2].12H_2O$; and $K_8[Cr_6(HPO_3)_{13}].52H_2O$, to be formed by mixing soln. of chromic chloride and potassium phosphite; likewise with sodium chromium phosphite, $Na_4[Cr(HPO_3)_2].14H_2O$; $Na[Cr(HPO_3)_2.Na_2HPO_4.73H_2O$; $Na_4[Cr_2(HPO_3)_5].39H_2O$; and ammonium chromium phosphite. A guanidine salt was also prepared. O. W. Gibbs prepared **ammonium phosphitohexamolybdate,** $(NH_4)_2O.6MoO_3.H_3PO_3.6H_2O$, by the action of soln. of ammonium molybdate on phosphorous acid. A. Rosenheim and M. Schapiro prepared a series of heteropolymolybdates with the general formula $2R_2O.P_2O_3.12MoO_3.nH_2O$, and also $2R_2O.P_2O_3.5MoO_3.nH_2O$. The former by dissolving phosphorous acid in an excess of alkali molybdate (say 1 : 6) acidifying the soln. with hydrochloric acid, and warming the liquid; and the latter by adding 2 mols of molybdium trioxide to a boiling aq. soln. of a mol of alkali phosphite, and allowing the liquid to crystallize. They thus obtained **ammonium phosphitododecamolybdate,** $2(NH_4)_2O.P_2O_3.12MoO_3.23H_2O$, and **ammonium phosphitopentamolybdate,** $2(NH_4)_2O.P_2O_3.5MoO_3.7H_2O$; M. Weinberg also reported an ammonium phosphitohexamolybdate, $(NH_4)_3[P(Mo_2O_7)_3].6H_2O$; M. Weinberg reported a **potassium phosphitohexamolybdate,** $K_2[P(Mo_2O_7)_3].11H_2O$; and A. Rosenheim and M. Schapiro, $2K_2O.P_2O_3.12MoO_3.9H_2O$(and $17H_2O$), and **potassium phosphitopentamolybdate,** $2K_2O.P_2O_3.5MoO_3.6H_2O$. They also obtained **lithium phosphitododecamolybdate,** $2Li_2O.P_2O_3.12MoO_3.19H_2O$; and

sodium phosphitododecamolybdate, $2Na_2O.P_2O_3.12MoO_3.19H_2O$(and $41H_2O$). W. Weinberg also prepared the salt $Na_3[P(Mo_2O_7)_3].10H_2O$, as well as a *guanidine salt*. O. W. Gibbs also reported **ammonium phosphitotungstate,** $6(NH_4)_2O.22WO_3.4H_3PO_3.25H_2O$; **potassium phosphitotungstate,** $5K_2O.32WO_3.16H_3PO_3.46H_2O$, as well as $5K_2O.24WO_3.2H_3PO_3.13H_2O$; and **sodium phosphitotungstate,** $2Na_2O.22WO_3.8H_3PO_3.35H_2O$; and W. Weinberg, **sodium phosphitohexatungstate,** $Na_3[P(W_2O_7)_3].16H_2O$. O. W. Gibbs reported ill-defined **copper phosphitotungstates,** and **mercurous phosphitotungstates.** A. Rodgers boiled for 5 hrs. a mixture of 1·5 grms. of ammonium phosphite, one gram of vanadium trioxide, 20 grms. of ammonium tungstate, 23 c.c. of aq. ammonia, and 700 c.c. of water; evaporated the mixture to one-third its original vol.; and obtained black octahedra of **ammonium tetraphosphitotetradecavanaditohenitricontatungstate,** $14(NH_4)_2O.2P_2O_3.7V_2O_3.31WO_3.78H_2O$.

V. Kohlschütter and H. Rossi noted the possible existence of **uranous phosphite;** and C. F. Rammelsberg obtained **uranyl phosphite,** $(UO_2)_3H_2(HPO_3)_4.12H_2O$, by adding ammonium uranate to an aq. soln. of phosphorus trichloride. The yellow precipitate loses 9·03 per cent. of moisture when dried over conc. sulphuric acid; 10·52 per cent. at 180°; 11·79 per cent. at 240°; and 16·45 per cent. at 300°. The residue is green. A. Rosenheim and H. Gläser prepared a series of alkali uranyl phosphites by adding a soln. of uranyl or sulphate drop by drop to a conc. soln. of alkali phosphite until the precipitate no longer dissolves when the mixture is vigorously shaken. The liquid on standing deposits deep yellow crystals. They thus obtained **potassium uranyl phosphite,** $K_2[UO_2(HPO_3)_2]$; **ammonium uranyl phosphite,** $(NH_4)_2[UO_2(HPO_3)_2]$; and **sodium uranyl phosphite,** $Na_2[UO_2(HPO_3)_2]$. M. Lobanoff obtained **uranium phosphite,** $U(HPO_3)_2.4H_2O$; and **uranium hydrophosphite,** $U(HPO_3)(H_2PO_3)_2$, by adding the requisite proportion of the acid to acidic soln. of uranic sulphate.

H. Rose, and C. F. Rammelsberg reported **manganous phosphite,** $MnHPO_3.H_2O$, by neutralizing an aq. soln. of phosphorus trichloride with ammonia, and adding a manganous salt. The precipitate is reddish-white. C. F. Rammelsberg dissolved manganous carbonate in phosphorous acid, and neutralized the soln. with sodium carbonate. When heated to redness in a retort the salt often becomes incandescent, and develops hydrogen along with phosphine, and some red phosphorus sublimes; the residue is mainly pyrophosphate mixed with phosphide, or, as C. F. Rammelsberg represented the reaction: $7MnHPO_3=3Mn_2P_2O_7+MnP+7H$. H. Rose said the salt dissolves with difficulty in water, but it dissolves readily in soln. of manganous chloride and sulphate. L. Vanino found the salt reacts slowly with potassium sulphide. A. Rosenheim, S. Frommer and W. Händler obtained deep violet-red soln. by mixing salts of tervalent manganese with soln. of alkali phosphites, but owing to hydrolysis obtained only impure *sodium manganese phosphite*. H. Rose prepared a **ferrous phosphite** by neutralizing an aq. soln. of phosphorus trichloride, and adding ferrous sulphate. The precipitate is washed with boiling water and dried. It is a white powder which readily oxidizes and becomes green. When heated it gives off hydrogen and forms ferrous pyrophosphate; the reaction may be accompanied by incandescence. J. A. Krenner described a reddish-brown ferrous phosphite, $nFeO.P_2O_3$, occurring as a mineral, which he named *schafarzikite*—after F. Schafarzik. The crystals are tetragonal pyramids with the axial ratio $a:c=1:9787$. L. Tokody gave 1 : 0·95381. The crystals are isomorphous with trippkeite. According to L. Tokody, the pleochroic crystals have ω straw-yellow, and ϵ brownish-yellow. The index of refraction is 1·740, the birefringence is feeble, and the optical character is positive. The sp. gr. is 4·3; and the hardness, 3·5. A. Rosenheim and co-workers could not prepare complex ferrous phosphites. B. Grützner obtained a soln. of **ferric phosphite** by dissolving ferric oxide in phosphorous acid. The precipitate obtained by adding water has a variable composition, but E. Berger showed that if the precipitate be thoroughly washed with cold water to remove all the phosphorous acid, the white powder has a constant composition, that of **ferric**

trihydroxyhexaphosphite, $2Fe_2(HPO_3)_3.Fe(OH)_3.5H_2O$. If, in the preparation of ferrous phosphite, the ferrous sulphate is replaced by ferric chloride or ammonium ferric sulphate, the white precipitate of ferric phosphite, $Fe_2(HPO_4)_3.9H_2O$, is soluble in an excess of the soln. of the ferric salt. If ammonia be in excess, a basic ferric phosphite may be formed. When the ferric salt is heated, H. Rose said that hydrogen and phosphine are given off, but C. F. Rammelsberg found only hydrogen, and a residual mixture of ferric pyrophosphate, and ferrous phosphate. A. Rosenheim, S. Frommer and W. Händler added a cold, conc. soln. of ferric chloride to a sat. soln. of ammonium or alkali phosphite, and obtained **sodium ferric hydroxyphosphite,** $Na_2[Fe(OH)(HPO_3)_2].20H_2O$; **potassium ferric hydroxyphosphite,** $K_2[Fe(OH)(HPO_3)_2].20H_2O$; and **ammonium ferric hydroxyphosphite,** $(NH_4)_2[Fe(OH)(HPO_3)_2].8H_2O$.

H. Rose obtained a red precipitate of **cobalt phosphite,** $CoHPO_3.2H_2O$, by treating a soln. of ammonium phosphite with cobalt chloride; and C. F. Rammelsberg, by treating cobalt carbonate with an aq. soln. of phosphorus trichloride. The dried salt is pale red, but after drying at 250°, is blue. It loses its water of crystallization at 250°. When calcined in a retort, the mass may become incandescent. C. F. Rammelsberg represented the reaction: $7CoHPO_3=3Co_2P_2O_7+CoP+7H$; and when evaporated with nitric acid, it yields the pyrophosphate. As in the case of the cupric salt, R. Kremann assumed the existence of *sodium cobaltophosphite*, $NaCoPO_3$. A. Rosenheim, S. Frommer and W. Händler treated a salt of bivalent cobalt with ammonium or potassium phosphite and obtained **ammonium cobalt phosphite,** $(NH_4)_2[Co_3(HPO_3)_4].18H_2O$; and **potassium cobalt phosphite,** $K_2[Co_3(HPO_3)_4].32H_2O$. H. Rose, and C. F. Rammelsberg prepared **nickel phosphite,** $NiHPO_3.H_2O$, by the methods employed for cobalt phosphite. According to H. Rose, nickel phosphite loses all its water at 250°; and when heated in a retort it gives off hydrogen alone, and, according to C. F. Rammelsberg, the residue is a mixture of the pyrophosphate with a trace of phosphide. When evaporated with nitric acid, nickel pyrophosphate is formed. R. Kremann assumed the existence of *sodium nickelophosphite*, $Na[NiPO_3]$. A. Rosenheim, S. Frommer and W. Händler treated a salt of bivalent nickel with an alkali or ammonium phosphite, and obtained **ammonium nickel phosphite,** $(NH_4)_2[Ni_3(HPO_3)_4].18H_2O$; and **potassium nickel phosphite,** $K_2[Ni_3(HPO_3)_4].32H_2O$.

§ 19. Metaphosphorous and Pyrophosphorous Acids and their Salts

According to H. J. van de Stadt,[1] if oxygen and phosphine, both thoroughly dried, be mixed slowly, a greenish-blue, often intermittent, combustion occurs and **metaphosphorous acid,** HPO_2, is formed: $PH_3+O_2=H_2+HPO_2$; and if the press. of the gases is low, crystals of the acid collect on the walls of the containing vessel. The crystals do not melt at 80°, and they react with water, forming phosphorous acid: $HPO_2+H_2O=H_3PO_3$.

It will be observed that ordinary phosphorous acid may be regarded as orthophosphorous acid, $P(OH)_3$, which has undergone some intramolecular change, forming $H-PO=(OH)_2$; if the meta-acid is regarded as a derivative of the ortho-acid by the loss of water, then the condensation of two mols of the ortho-acid, with the loss of water, will furnish normal **pyrophosphorous acid,** $H_4P_2O_5$:

$HO-P=O$

Metaphosphorous acid, HPO_2.

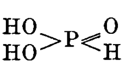
$HO=P<\genfrac{}{}{0pt}{}{OH}{OH}$

Orthophosphorous acid, H_3PO_3.

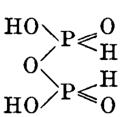
$O<\genfrac{}{}{0pt}{}{P=(OH)_2}{P=(OH)_2}$

Pyrophosphorous acid, $H_4P_2O_5$.

Owing to the peculiar intramolecular change which attends the conversion of orthophosphorous acid into ordinary phosphorous acid, it is probable that the normal pyrophosphorous suffers a similar change whereby the phosphorus passes to the quinquevalent form:



Phosphorous acid.



Pyrophosphorous acid.

In 1864, N. Menschutkin first obtained a derivative of pyrophosphorous acid in the form of acetopyrophosphorous acid, $H_3(C_2H_3O)P_2O_5$. In 1888, L. Amat showed that the secondary phosphites lose water when heated, forming pyrophosphites; which can be regarded as derivatives of a special pyrophosphorous acid, so that H_3PO_3 is related to $H_4P_2O_5$, the same as H_3PO_4 is related to $H_4P_2O_7$. He obtained a soln. of the very unstable pyrophosphorous acid by treating at as low a temp. as practicable a dil. soln. of barium pyrophosphite with an eq. amount of dil. sulphuric acid. He estimated the heat of decomposition to be $H_4P_2O_{5aq.}=2H_3PO_{3aq.}+4{\cdot}9$ Cals.; and the heat of neutralization: $H_4P_2O_{5aq.}+2NaOH_{aq.}=Na_2H_2P_2O_{5aq.}+2H_2O+28{\cdot}6$ Cals. L. Amat made about half a dozen pyrophosphites. In aq. soln., they readily form hydrophosphites: $Na_2H_2P_2O_5+H_2O=2POH(ONa)(OH)$, and this the more rapidly, the greater the conc. of the soln., and the higher the temp. Increasing the acidity of the soln.—by, say, sulphuric acid—also accelerates the reaction. The thermal properties of the pyrophosphites are said by L. Amat to prove that they are not ordinary hydrophosphites.

L. Amat prepared **sodium dihydropyrophosphite**, $Na_2H_2P_2O_5$, in vacuo at about 160° until it has lost its water. The product is freely soluble in water, and the aq. soln. is unlike one of sodium hydrophosphite in that it is neutral to both methyl-orange and phenolphthalein. The soln. is stable when cold, but when boiled, it is converted into the hydrophosphite; it is the more stable, the less its conc., but a conc. soln. can be evaporated for crystallization. The presence of acids lessen the stability of the soln. The rate of conversion follows the mass law. The change is more rapid the more conc. the soln., but the effect of dilution becomes smaller and smaller as the conc. diminishes. With soln. so dil. that the concentration is without influence, the rate of change is proportional to the quantity of acid present. Nitric and hydrochloric acids exert the greatest effect, sulphuric acid somewhat less, and phosphorous acid still less, whilst acetic acid has only a very slight effect. The change in presence of alkali is subject to similar laws, the rate of change at each instant being proportional not only to the quantity of pyrophosphite present in the soln. but also to the quantity of free alkali. The heat of hydrolysis: $Na_2H_2P_2O_{5solid}+H_2O_{solid}=2NaH(HPO_3)_{solid}+6{\cdot}24$ Cals.; and the heat of soln. at 13° is 0·3 Cal. The corresponding **potassium dihydropyrophosphite** was made in a similar way. White **calcium dihydropyrophosphite**, $CaH_2P_2O_5$, was made by heating the monohydrated hydrophosphite for 2 days at 150°. The salt is not completely soluble in water, but is freely soluble in hydrochloric acid. The soln. with both solvents smell of phosphine. The analogous **strontium dihydropyrophosphite**, $SrH_2P_2O_5$, and likewise **barium dihydropyrophosphite**, $BaH_2C_2O_5$, were prepared by heating the monohydrated hydrophosphite for 150 hrs. at 120°–150°. L. Amat also made **thallium dihydrophosphite**, $Tl_2H_2P_2O_5$, and **lead dihydropyrophosphite**, $Pb_2H_2P_2O_5$, in a similar way. When a soln. of sodium dihydropyrophosphite is treated with lead nitrate, the lead nitratophosphite is formed. The lead salt is readily hydrolyzed by water.

§ 20. Phosphorus Tetroxide or Phosphorosic Oxide

According to T. E. Thorpe and A. E. H. Tutton,[1] when phosphorus glows in air at ordinary temp., phosphoric oxide is the only oxide of phosphorus formed; at higher temp.—about 50°–60°—phosphorous oxide begins to appear, but only when the phosphorus is ignited does any considerable proportion of that oxide appear. This is in agreement with the observations of R. Cowper and V. B. Lewes,

N. Blondlot, indeed, believed that phosphoric oxide is always the primary product, and that the phosphorous oxide is the result of a secondary reaction: $3P_2O_5+4P=5P_2O_3$. M. Pagels said that the proportion of phosphorous to phosphoric oxide rarely exceeds 1:3, but T .E. Thorpe and A. E. H. Tutton obtained a ratio nearly 1:1. In addition to these oxides, when phosphorus burns at a moderately high temp. in a limited supply of air, phosphorus tetritoxide is formed (*q.v.*). P. Hautefeuille and A. Perrey obtained a crystalline sublimate by heating the products of the combustion of phosphorus, but they regarded it as an allotropic form of phosphoric oxide. T. E. Thorpe and A. E. H. Tutton showed that the sublimate was more probably a specific oxide. According to T. E. Thorpe and A. E. H. Tutton, if the mixed oxides formed by the slow burning of phosphorus in air dried by phosphorus pentoxide be heated in an evacuated sealed tube at about 290°, the white mass becomes orange or red, and a sublimate of transparent, lustrous crystals is formed. C. A. West employed a somewhat similar mode of preparation. V. Kohlschütter and A. Frumkin observed that some tetroxide is formed by the decomposition of the red deposit produced when phosphorus oxidizes in oxygen at a low press.; E. J. Russell, when the white deposit formed by oxidizing phosphorus in oxygen at a high press. is heated in vacuo; and C. C. Miller, when phosphorus trioxide oxidizes in moist oxygen at 25° and 600 mm. press.

The analysis of the oxide by T. E. Thorpe and A. E. H. Tutton, and C. A. West corresponds with the empirical formula PO_2. The former workers assumed that this oxide is analogous with nitrogen and antimony tetroxides. C. A. West found that the vap. density at a temp. exceeding 1400° was 229·3, hydrogen unity; hence the mol. wt. is 458·6, corresponding with the formula P_8O_{16}. This oxide does not therefore fall in line intermediate between phosphorous oxide, P_4O_6, and phosphoric oxide, P_4O_{10}. No suitable solvent is known to enable the cryoscopic and ebulliscopic methods to be applied. The term **phosphorus tetroxide** is therefore a misnomer, although it is usually retained because it has crept into the literature of the subject. Similar remarks apply to many other compounds—*e.g.* phosphorus trioxide and pentoxide, etc. It might also be called *phosphorosophosphoric oxide*, a term which can be abbreviated to **phosphorosic oxide.** According to T. E. Thorpe and A. E. H. Tutton, phosphorosic oxide cannot be regarded as the anhydride of hypophosphoric acid—*vide infra*—even though its composition has a formal resemblance to that of the unknown *hypophosphoric anhydride*, because hypophosphoric acid exerts no reducing action on the chlorides of mercury, gold, or silver, and forms a sparingly soluble sodium salt. The aq. soln. of phosphorosic oxide does not possess these properties. Phosphorosic oxide is not to be regarded as a mere compound of phosphorous and phosphoric oxides, and it is derived from phosphorous oxide either by the elimination of red phosphorus: $2P_4O_6=3P_2O_4+2P$, or of phosphorus tetritoxide: $7P_4O_6=2P_4O+10P_2O_4$.

Phosphorosic oxide forms white rhombic crystals which on a cursory glance seem to be cubical. The polarization phenomena do not agree with those of tetragonal crystals, and their holosymmetry is not in agreement with hexagonal crystals. The crystals were far too deliquescent in air to allow the crystallographic measurements to be made. C. A. West found the sp. gr. to be 2·537 at 22·6°/4°. Heat does not cause any appreciable change; the crystals sublime without melting and without decomposition. T. E. Thorpe and A. E. H. Tutton said that no visible change occurs at 100°, but sublimation proceeds at 180°. C. A. West found that a sample exposed for 12 months to daylight suffered no visible change. The general reactions of phosphorosic oxide in aq. soln. shows that it probably breaks down into phosphorous and metaphosphoric acids: $2PO_2+2H_2O=HPO_3+H_3PO_3$. Attempts to determine the relative proportions of the two acids did not yield concordant results.

The aq. soln. was found by T. E. Thorpe and A. E. H. Tutton to require repeated evaporation with *nitric acid* in order to oxidize the phosphorosic oxide to phosphoric acid. An aq. soln. of the oxide neutralized with *sodium hydroxide* behaves like a soln. of normal sodium phosphite. A boiling soln. of soda-lye does not affect phosphites, but decomposes hypophosphites into a phosphate with the elimination of hydrogen ; a soln. of phosphorosic oxide in water behaves towards *silver nitrate* like a soln. of the same oxide which has been boiled with soda-lye. In both cases, a white or yellow precipitate is formed which quickly turns brown and finally black. In aq. soln., *calcium chloride* gives no precipitate at first, but a flocculent white precipitate is obtained on adding ammonia ; *barium chloride or hydroxide* gives a white precipitate, soluble in hydrochloric acid, but not soluble in acetic acid. An ammoniacal soln. of *magnesium chloride—magnesia mixture*—gives no precipitate with phosphites and hypophosphites except in very conc. soln. ; with a soln. of phosphorosic oxide, there is an immediate precipitate of what C. A. West called magnesium metaphosphate, and T. E. Thorpe and A. E. H. Tutton, ammonium magnesium phosphate. A soln. of *mercuric chloride* gives a white precipitate which forms slowly hot or cold ; *lead nitrate* gives a white precipitate insoluble in acetic acid ; and a hot or cold soln. of *potassium permanganate* is slowly decolorized. According to C. A. West, *benzene, naphthalene, phenol, nitrobenzene, chloroform, carbon disulphide,* and *ether* seemed to be entirely without action on the oxide, whilst *acetone* was turned slightly brown and *acetic acid* became deep brown. This action seems to resemble that of the commercial phosphorus pentoxide on acetic acid.

§ 21. Hypophosphoric Acid

In 1877, T. Salzer,[1] in his memoir : *Ueber die Unterphosphorsäure,* proved that B. Pelletier's *acide phosphatique* contained an acid previously unrecognized. It is now called **hypophosphoric acid,** $H_4P_2O_6$, or H_2PO_3 ; and sometimes *subphosphoric acid.* The phosphatic acid is prepared by the slow oxidation of phosphorus in air in the presence of water as indicated in connection with phosphorous acid. T. Salzer prepared the *acidum phosphori per deliquium* by placing sticks of phosphorus in glass cylinders half covered with water. The cylinders were suspended by a string in an earthenware mug loosely covered with a sheet of glass. Every third day the liquid in the cylinders was collected, and the sticks of phosphorus again half covered with water. He added that the oxidation of the phosphorus is much assisted, if large quantities are left to the action of the air and water in the same space. This is effected, probably not by rise of temp., but by the stronger ozonizing of the air, or otherwise by the more active formation of hydrogen peroxide, for the phosphorus is most corroded where it dips into the liquid. It is also remarked that the formation of the hypophosphoric acid proceeds with that of the phosphorous and phosphoric acids in a certain ratio, until the liquid becomes so conc. that no more of the first acid can be formed : only about 6 or 7 per cent. of the phosphorus is converted into hypophosphoric acid, phosphoric acid being the chief product. The hypophosphoric acid was separated in the form of a sparingly soluble sodium salt by treating the acid with the alkali carbonate or acetate. A. Joly found that the oxidation of the phosphorus in the preparation of phosphatic acid occupies 48 hrs. in summer, and longer in winter. In summer, 10 per cent. of the phosphorus is oxidized to this acid, and in winter 12–14 per cent. According to A. Rosenheim, W. Stadler, and F. Jacobsohn, the phosphorus is oxidized very slowly below 5°, and above 10°, the oxidation is so rapid that marked quantities of meta- and orthophosphoric acids are produced in consequence of local heating on the surface of the sticks of phosphorus. A. Joly obtained sodium hypophosphate by adding sodium carbonate to the boiling acid until neutral to methyl-orange ; when the liquid, conc. by evaporation, is cooled, the sodium salt separates. It is washed with cold water, and recrystallized from boiling water as $Na_2H_2P_2O_6.6H_2O$. T. Salzer said that the sodium salt can be prepared directly by exposing in air sticks of phosphorus partially immersed in a dil. soln. of sodium chloride (1 : 100). P. Drawe recommended T. Salzer's process for preparing *le acide phosphatique,* but he preferred collecting the oxidation products in a 25 per cent. soln. of sodium acetate in place of water. C. Bansa used a similar process. H. Schuh compared the different modes of preparing the acid.

J. Cavalier and E. Cornec's method of preparing hypophosphoric acid by the slow oxidation of phosphorus in the presence of water, is as follows: Glass rods are placed horizontally on a photographic dish : sticks of phosphorus are placed transversely over the rods, and glass rods are placed between the sticks of phosphorus to prevent their touching, and so possibly igniting. Water is poured into the dish until the sticks of phosphorus are half submerged. The dish is kept in a cool place, and covered with a glass plate with a roll of wadding as intermediary so that filtered air can slowly find its way into the dish. With a dish 13 × 18 cms., it is possible to get 30–50 grms. of the sodium salt in 5–6 days. The acid liquor is treated for the sodium salt as already described.

T. Salzer found that hypophosphoric acid is formed during the slow oxidation of phosphorous acid in air. Hypophosphoric acid is an intermediate product in the oxidation of phosphorus by cupric nitrate in the presence of dil. nitric acid, and J. Corne prepared hypophosphites by this process in 1882—ammonia, and phosphorous and phosphoric acids were by-products. P. Drawe adversely criticized this process. J. Philipp substituted silver nitrate for cupric nitrate. F. Tauchert observed that this acid is one of the products of the action of phosphorus on a soln. of copper sulphate. A. Sänger obtained the silver hypophosphate by oxidizing phosphorous acid with silver nitrate in neutral or ammoniacal soln. In this reaction, it is assumed that $8AgNO_3+2H_3PO_3+H_2O+8NH_3=Ag_4O+Ag_4P_2O_6+8NH_4NO_3$, and the silver oxide formed oxidizes the phosphorous acid to hypophosphoric acid. A. Rosenheim and J. Pinsker did not recommend this mode of preparation.

In A. Rosenheim and J. Pinsker's modification of J. Corne's process, 100 grms. of copper turnings are added to a mixture of 100 c.c. of water and 200 c.c. of nitric acid (sp. gr. 1·4) in a 3-litre flask. When the intensity of the reaction has subsided, yellow phosphorus is gradually added while the temp. is maintained between 50° and 70°. When the clear colourless liquid is decanted off, the copper is all precipitated as copper phosphide and spongy copper, and half is neutralized with sodium carbonate, and mixed with the other half. Crystals of the sodium salt, $Na_2H_2P_2O_6.4H_2O$, separate after a time. The yield with copper nitrate is 10 per cent. of the theoretical, but is not so good if silver nitrate is used in place of copper.

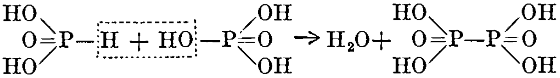
A. Rosenheim and J. Pinsker showed that zinc, manganese, nickel, cobalt, mercuric, and ferric nitrates do not give appreciable amounts of hypophosphoric acid—neither do the nitrogen oxides—if used in place of Corne's copper nitrate. A. Rosenheim and J. Pinsker consider that the formation of the acid is due to the action of the copper and not of the nitric acid since other salts of copper furnish hypophosphoric acid when treated with yellow phosphorus; according to F. Tauchert (1913), there are two reactions: $5Cu(NO_3)_2+4P+8H_2O=Cu_3P_2+2Cu+10HNO_3+2H_3PO_4$; and $4Cu(NO_3)_2+4P+6H_2O=H_4P_2O_6+Cu_3P_2+Cu+8HNO_3$—about 7 per cent. of the phosphorus is thus obtained as hypophosphoric acid, while as much as 20 per cent. may be effective with a hot soln. of copper sulphate. The nitric acid further reacts with the copper phosphide, forming phosphoric and phosphorous acids and nitric oxide. A. Rosenheim and J. Pinsker obtained as high as 60 per cent. yields of hypophosphoric acid by the electrolysis of 1–2 per cent. sulphuric acid soln. with copper, nickel, or silver phosphide as anode, and the corresponding metal as cathode. The phosphide is decomposed, and the phosphorus is oxidized to the acid. They used a current of 3–10 volts. With a cathode of iron phosphide, the oxidation was carried further and phosphoric acid alone was obtained.

T. Salzer isolated the acid by dissolving the sodium salt in hot water, and treating the soln. with lead acetate when an insoluble lead hypophosphate is precipitated. This salt is filtered from the soln. and washed with hot water. The precipitate is suspended in water, and a current of hydrogen sulphide passed through the soln. Lead sulphide is precipitated, and a soln. of free hypophosphoric acid is obtained. On evaporation, the excess of hydrogen sulphide is driven from the soln., but the evaporation cannot be carried very far without decomposing the acid. Hence, the soln. must be further evaporated in a desiccator in vacuo over sulphuric acid. This method is tedious, and not so good as when the barium salt is used in place of the lead salt. T. Salzer, A. Sänger, and A. Joly preferred to convert the sodium salt into the insoluble barium hypophosphite, which was then decomposed by treatment with an eq. amount of sulphuric acid. The filtered soln. was conc. in vacuo over sulphuric acid. In time crystals of the hydrate $H_2PO_3.H_2O$, or $H_4P_2O_6.2H_2O$, separate. A. Joly added that in preparing the acid, an elevation of temp., and an excess of sulphuric acid, should be avoided. The crystals of the hydrated acid are liable to decompose if left too long in contact with the mother-liquor.

Analyses by T. Salzer, A. Sänger, and A. Joly are in agreement with the empirical formula H_2PO_3. At first, T. Salzer considered the phosphorus hypophosphoric acid to be quadrivalent, and wrote the formula $O{=}P(OH)_2$, but he later gave up this idea after he had prepared four sodium salts:

Primary.	Secondary.	Tertiary.	Quaternary.
$MH_3P_2O_6$	$M_2H_2P_2O_6$	$M_3HP_2O_6$	$M_4P_2O_6$

and he accepted J. Volhard's suggestion that hypophosphoric acid is formed by the condensation of a mol each of phosphorous and phosphoric acids by the elimination of water: $(HO)_2{=}PO{-}\boxed{OH{+}H}O{-}P(OH)_2{\rightarrow}H_2O{+}(HO)_2P.O.P(OH)_2$. Assuming that the phosphorus in phosphorous acid is quinquevalent, this becomes $(HO)_2:PO{-}H{+}OH{-}PO:(OH)_2{=}H_2O{+}(HO):$



T. Salzer quoted the action of bromine on the acid: $Na_4P_2O_6{+}Br_2{+}H_2O{=}2NaBr{+}Na_2H_2P_2O_7$, in support of this hypothesis. According to W. Rosenheim and co-workers, the f.p. curve of mixtures of phosphorous and phosphoric acids, Fig. 37, lends no support to J. Volhard's hypothesis, since it shows no signs of the formation of a chemical compound or an isomorphous mixture of the two acids; and hypophosphoric acid cannot be formed by fusing together these two acids by some such reaction as that symbolized $H_3PO_3{+}H_3PO_4{=}H_2O{+}H_4P_2O_6$. Hence, while mixtures of phosphoric and phosphorous acids behave like mixtures, hypophosphoric acid behaves like a chemical individual. Reviewing the main arguments which have been advanced in support of one or other of the hypotheses as the mol. formula of hypophosphoric acid—H_2PO_3, or $H_4P_2O_6$—there is (1) T. Salzer's reported series of primary, secondary, tertiary, and quaternary salts. (2) A. Joly found that the heat of neutralization of hypophosphoric acid agrees better with a dibasic acid, H_2PO_3, than with a tetrabasic acid, $H_4P_2O_7$. On neutralizing hypophosphoric acid with potassium hydroxide, methyl-orange changes in tint when one eq. of potassium has been added per eq. of phosphorus; litmus changes with 1·5 eq. of potassium under the same conditions; and phenolphthalein commences to change tint with 1·5 of potassium, and the change is completed when two eq.

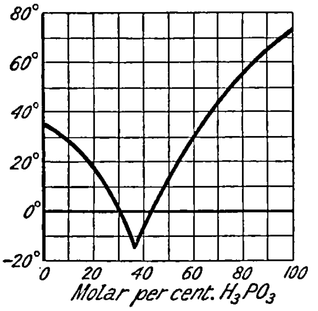


FIG. 37.—Freezing-point Curves of Mixtures of Phosphorous and Phosphoric Acids.

of potassium have been added. (3) H. Dufet considers that the isomorphism of sodium pyro- and hypophosphates agrees with the assumption that they have similar formulæ. The crystalline forms certainly have a quasi-identity, but even if the crystals are really isomorphous, the formulæ of the salts are not chemically analogous, for neither $Na_4P_2O_6.10H_2O$ nor $Na_2PO_3.5H_2O$ resembles $Na_4P_2O_7.10H_2O$. With the doubled formula for sodium hypophosphate, these salts have the same number of sodium and phosphorus atoms per mol, and approximately the same crystalline form, sp. gr., and mol. vol. (4) N. Parravano and C. Marini have argued in favour of the doubled formula $Na_4P_2O_6$ because the salts $Na_4P_2O_6.MoO_3$; $Na_4P_2O_6.2MoO_3$; $Na_4P_2O_6.3MoO_3$; and $Na_4P_2O_6.4MoO_3$ furnish anions $P_2O_6.MoO_3$; $P_2O_6.2MoO_3$; etc. The argument is a *non sequitur* because it might also be said that $2PO_3$ is always united with at least a mol. eq. of MoO_3. (5) A. Rosenheim and J. Pinsker compared the electrical conductivity μ of phosphoric, phosphorous, hypophosphorous, and hypophosphoric acids, and found

	Phosphoric acid.	Hypophosphoric acid.	Phosphorous acid.	Hypophosphorous acid.
Dilution, $v=16$ . .	124	184	222	245
Dilution, $v=1024$.	341	370	358	367

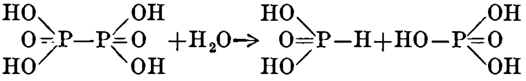
and hence inferred that the formula is probably H_2PO_3. The opposite conclusion might be inferred by comparing the conductivity of the acid regarded as $H_4P_2O_6$, with pyrophosphoric acid, $H_4P_2O_7$, for at dilution $v=1024$, μ is respectively 608 and 616. Opposite conclusions have also been drawn by A. Rosenheim, W. Stadler, and F. Jacobsohn from measurements of the conductivities of the phosphorus acids to those drawn by N. Parravano and C. Marini, and E. Cornec applied to the two sodium salts, $Na_2H_2P_2O_6$ and $Na_4P_2O_6$, points to the tetrabasic formula, $H_4P_2O_6$. (6) According to A. Rosenheim and J. Pinsker, the f.p. of aq. soln. of hypophosphoric acid and its salts resemble those of pyrophosphoric acid and its salts, and correspond with the formula $H_4P_2O_6$; but it has been argued that this molecular weight really represents associated mols. $(H_2PO_3)_2$ and not the mol. $H_4P_2O_6$ of a tetrabasic acid. (7) E. Cornec found that the progressive neutralization of the acid by potassium hydroxide gives a well-defined minimum corresponding with $K_4P_2O_6$. (8) R. G. van Name and W. J. Huff found that the speed of hydrolysis of the acid favours the assumption that the mol formula is $H_4P_2O_6$. (9) P. Walden found the formula connecting the heat of fusion and the surface tension with the mol. wt. is in agreement with the formula H_2PO_3. (10) A. Rosenheim and co-workers also found that the effect of methyl pyrophosphite, $(CH_3)_2PO_3$, and ethyl pyrophosphite, $(C_2H_5)_2PO_3$, on the b.p. of ethyl iodide or bromide, or chloroform, is in agreement with the simpler formula H_2PO_3 in place of $H_4P_2O_6$. Against this argument, however, E. Cornec has shown that there is probably a decomposition of the ethers at the b.p., and he found that the methyl ester lowered the f.p. of benzene as if its mol. weight were between 220 and 236, in agreement with the formula $(CH_3)_4P_2O_6$—theory 218. Even if the ethers did have the simpler formula, it would make it more probable but would not prove that the acid had the simpler formula because M. Meslans found that the hydrofluoric ethers—*e.g.* ethyl fluoride —have the simple formulæ RF, while the acid itself has probably the doubled formula H_2F_2. The cryoscopic behaviour of the free acid, as well as that of the potassium salt, is in agreement with the doubled formula for hypophosphoric acid. A. Rosenheim and J. Pinsker added that the higher value for the mol. wt. of this acid deduced from the cryoscopic observations, is due to the association of the simpler mols., H_2PO_3, because the mol. conductivity of aq. soln. is abnormally high if the formula is taken as $H_4P_2O_6$, and the figures so obtained ($\mu=267\cdot4$ for $v=31\cdot6$; $\mu=608\cdot8$ for $v=1111\cdot2$) are not in accordance with the properties of hypophosphoric acid. Moreover, the mol. conductivity can be brought into line with the mol. conductivities of the other acids of phosphorus only when the formula is taken as H_2PO_3. R. G. van Name and W. J. Huff do not agree with this—*vide infra*, electrical conductivity.

The fact that phosphorus tetroxide, P_2O_4, furnishes phosphoric and phosphorous acids when treated with water is expressed by the structural formula $O{=}P{\equiv}O_3{\equiv}P$. If phosphorus tetroxide be the anhydride of hypophosphoric acid—*vide supra*—it might be anticipated that $O{=}P{\equiv}O_3{\equiv}P+2H_2O \rightarrow O(OH)_2P-O-P(OH)_2$. If the last formula really represented the structure of hypophosphoric acid, it would follow that (i) this acid would be a reducing agent like phosphorous acid, but it is not; and that (ii) it ought to be possible to prepare at least two isomers by the action of sodium hydroxide on dipotassium hypophosphate, and of potassium hydroxide on disodium hypophosphate, say:

$$\begin{matrix}KO\\KO\end{matrix}\!>\!PO-O-P\!<\!\begin{matrix}ONa\\ONa\end{matrix}$$

$$\begin{matrix}NaO\\NaO\end{matrix}\!>\!PO-O-P\!<\!\begin{matrix}OK\\OK\end{matrix}$$

where in one case the KO-radicles are united to quinquevalent phosphorus, and in the other to tervalent phosphorus; other isomers should also be possible. As a matter of observation, the solubility, crystalline form, action of heat, water of crystallization, of the dipotassium disodium hypophosphate prepared in different ways are "völlig identisch." With the symmetrical formula, the decomposition into phosphoric and phosphorous acids is well represented by the following scheme:



Hypophosphoric acid. Phosphorous acid. Phosphoric acid.

phosphorus tetroxide also decomposes into the same two acids in contact with cold water, and this would favour the symmetrical structure:

With two mols. of water, such an acid would give hypophosphorous acid; and with three mols. of water, a mixture of phosphoric and phosphorous acids. The mol. formula of the acid cannot be established by graphic diagrams, even if it be so demonstrated that such a formula is in harmony with the generally accepted valency of phosphorus. The formula H_2PO_3 seems to require the unusual assumption that phosphorus is quadrivalent, $O{=}P{=}(OH)_2$, although inorganic chemists have sometimes stretched the valency hypothesis as occasion demands. The evidence is indecisive.

Two hydrated hypophosphoric acids have been reported. A. Joly found that when an aq. soln. of the acid is evaporated to dryness in vacuo, crystals of **dihydrated hypophosphoric acid,** $H_4P_2O_6.2H_2O$, are formed. The four-sided, rectangular plates are probably rhombic. They are very deliquescent, and are very soluble in water. They lose their water of crystallization in vacuo, and form the anhydrous acid. Assuming that hypophosphoric acid, $H_4P_2O_6$, m.p. 70°, corresponds with the above formula, $(OH)_2OP-PO(OH)_2$, the hydrate $H_4P_2O_6.2H_2O$, melting at 62°, is sometimes regarded as a kind of *orthohypophosphoric* acid: $(HO)_4P-P(OH)_4$, and the ordinary acid as *metahypophosphoric acid*, $(HO)_2OP-PO(OH)_2$. The dihydrate melts at 62°–62·5°—A. Rosenheim and M. Pritze gave 62°. A. Joly added that the undercooled liquid gradually deposits a mass of snow-like crystals of what is probably the anhydrous acid. The mother-liquor no longer solidifies completely when seeded by a crystal of the original hydrate. If the dihydrate is kept over sulphuric acid, it effloresces, forming a mass whose m.p. falls to 55°—that of the anhydrous acid. If kept away from moisture, the dihydrate is quite stable. Water decomposes the acid into a mixture of phosphoric and phosphorous acids. If the dihydrate be kept in the molten state for some time, it gradually decomposes, and the mother-liquor remaining after crystallization contains phosphorous acid. According to A. Sänger, **monohydrated hypo-**

phosphoric acid, $H_4P_2O_6.H_2O$, is obtained in cubical crystals, when the aq. soln. is evaporated over sulphuric acid in a vacuum. The hydrate melts between 79·5° and 81·5°, and decomposes, forming a mixture of phosphoric and phosphorous acids. The mother-liquor contains some phosphorous and phosphoric acids. A. Joly suggested that this hydrate is really a mixture of the anhydrous acid and the dihydrate, and is not a chemical individual. A. Rosenheim and M. Pritze also say that the existence of this hydrate is doubtful; and that the only stable hydrate between 0° and 60° is the dihydrate. J. Kendall and co-workers studied the relations of these hydrates with those of related acids.

As previously indicated, small crystals of the anhydrous acid, $H_4P_2O_6$, are formed by drying the dihydrate in vacuo. A. Rosenheim and M. Pritze could not obtain the anhydrous acid. According to A. Joly, the acid is hygroscopic, and melts at 55°, forming a colourless, transparent liquid which completely solidifies when seeded with a fragment of the original solid. If the temp. be allowed to rise suddenly to about 70°, the acid suddenly decomposes with a considerable rise of temp.—say to 99·5°—into a mixture of metaphosphoric and phosphorous acids without loss of weight: $H_4P_2O_6=H_3PO_3+HPO_3$. Water is evolved when the acid is heated over 100°, and phosphine comes off about 180°. T. Salzer found that the sp. gr. of the aq. soln. of the acid containing the eq. of 4·1 and 12·3 per cent. PO_4 are respectively 1·036 and 1·122. According to A. Joly, the heat of fusion of the anhydrous acid is 3·85 Cals., and of the dihydrate, —4·4 Cals.; the heat of soln. of the crystalline dihydrate is —1·1 Cals. A. Joly found that the heats of neutralization of an aq. soln. of the acid with soda-lye, H_2PO_3+N-NaOH at 10°–11° are:

NaOH	0·5*N*-	*N*-	1·5*N*-	2*N*-	3*N*-
Heat evolved	7·57	15·05	21·36	27·11	27·65 Cals.

Since the heat developed by the 1st, 2nd, and 3rd eq. of alkali progressively increases, it would appear as if the acid here behaves as if it were dibasic. E. Cornec examined the effect of the progressive neutralization of hypophosphoric acid by potassium hydroxide on its f.p., and the resulting curve is lowered down to that required for the normal salt, $K_4P_2O_6$. There are breaks in the curve indicating the existence of the primary, secondary, tertiary, and quaternary salts. Analogous results were obtained with aq. ammonia and hypophosphoric acid. The behaviour of the acid is very similar to that of pyrophosphoric acid.

Measurements of the electrical conductivity of hypophosphoric acid were made by N. Parravano and C. Marini, by A. Rosenheim and J. Pinsker, and R. G. van Name and W. J. Huff. For soln. with a mol of the acid in v litres of water, J. Pinsker found at 25·6°:

v	8	16	32	64	128	256	512	1024
μ	153·8	173·6	187·2	218·2	242·0	268·8	298·4	319·0

According to R. G. van Name and W. J. Huff, these results are somewhat too low. The acid is more or less hydrolyzed. At the lower dilutions, the conductivity of the pure acid is larger than an eq. mixture of phosphorous and phosphoric acids, while at higher dilutions, this relation is reversed. A. Rosenheim and J. Pinsker argued that the mol. conductivity, referred to the H_3PO_3-formula, is of the same order of magnitude as the mol. conductivities of phosphorous and phosphoric acids:

	v	16	32	64	128	256	512
μ	H_3PO_3	222	257	292	318	337	351
	H_3PO_4	124	156	195	240	279	317
	Mean	173	206·5	243·5	279	308	334

and seems to tend on dilution towards the same limit. This tendency is to be expected if the normal mol. were H_2PO_3 since the anions HPO'_3, $H_2PO'_3$, and $H_2PO'_4$ on account of their similarity in structure would probably have nearly the same velocities. R. G. van Name and W. J. Huff showed that the phenomenon is equally well explained by the $H_4P_2O_6$-formula. Owing to the high velocity of the hydrogen ion, the conductivity of $\frac{1}{2}(H^{\cdot}+H^{\cdot}+H_2P_2O''_6)$ would be nearly the same as that of $(H^{\cdot}+HPO'_3)$. That two and only two of the eq. of hydrogen in the mol. $H_4P_2O_6$, are extensively ionized is indicated by the fact that two of these eq. of hydrogen, but not the third, can be titrated in the presence of methyl-orange. On the assumption that the anion is HPO'_3, A. Rosenheim and W. Reglin found the transport number to be 0·425 with a 0·1*N*-soln. of $NaHPO_3.3H_2O$, at 16°. The transport number at 16° is 25·4, and at 25°, 31·6.

The conc. soln. of hypophosphoric acid is a syrupy liquid which tastes acid. P. Schulz said that the hypophosphates act as poisons. According to A. Rosenheim and J. Pinsker, the acid reacts as if it were monobasic towards alkali hydroxides, using methyl-orange as indicator and as if it were hemitribasic with phenolphthalein. T. Salzer found that **hydrogen** *in statu nascendi*—from zinc and sulphuric acid—has no action. The soln. of purified hypophosphoric acid in **water** can be kept for a time, and even boiled without change, but when the soln. is conc., decomposition takes place if the temp. exceeds 30°. With long keeping, however, the acid is hydrolyzed: $H_4P_2O_6+H_2O=H_3PO_3+H_3PO_4$. A 5 per cent. soln. did not contain a trace of hypophosphoric acid after being kept for 3 years. The hydrolysis thus yields an equimolar mixture of phosphorous and phosphoric acids; it is non-reversible; it is accelerated by acids; and since soln. of acidic sodium hypophosphate are stable at room temp. for long periods, the $H^{\cdot}$-ion conc. is below the turning-point of methyl-orange, 10^{-4}, and the hydrolysis at moderate temp. is negligible. Distinctly alkaline soln. are more stable. R. G. van Name and W. J. Huff measured the speed of hydrolysis in the presence of hydrochloric acid at 25° and 60°, and found that in dil. soln. where the hydrogen ion conc. is approximately normal, the reaction is unimolecular: $H_4P_2O_6+H_2O=H_3PO_3+H_3PO_4$, and not $2H_2PO_3+H_2O=H_3PO_3+H_3PO_4$. The mean value of the velocity coeff. rises from 0·000186 at 25° to 0·00631 at 60°. In general, the results of the hydrolytic decomposition of hypophosphoric acid cannot be ignored except in special cases where temp., acidity, conc., and time have exceptionally low values. Acid soln. of hypophosphates cannot be boiled without loss, nor can they safely be conc. by heat, and even at room temp. there will be serious danger of loss (*a*) in soln. containing a large excess of other mineral acids, and (*b*) when the hypophosphate itself is present in high conc., as is the case, for example, in conc. soln. of pure hypophosphoric acid. According to A. Sänger, A. Rosenheim and M. Pritze, and J. Kendall and co-workers, there are indications of the formation of a *monohydrate*, $H_4P_2O_6.H_2O$, and of a *dihydrate*, $H_4P_2O_6.2H_2O$. The acid is not affected by **hydrogen dioxide.** Indeed, hypophosphoric acid is to be regarded only as a very weak reducing agent. The **halogens,** at atm. press., do not change the free acid. The aq. soln. of hypophosphoric acid is not changed in the cold by the mineral **acids**; but when the temp. is raised, hydrolysis occurs and phosphorous and phosphoric acids are formed. No perceptible change occurs when hypophosphoric acid is treated with **hydrogen sulphide,** or with **sulphur dioxide**; and dil. **sulphuric acid** slowly hydrolyzes hypophosphoric acid when the soln. is boiled. The dil. soln. is not affected by dil. **nitric acid,** even when boiled; if the soln. is evaporated, however, nitric acid breaks down the hypophosphoric acid, and oxidizes the liberated phosphorous acid.

According to T. Salzer, **sodium chloride** makes the soln. slowly become turbid owing to the formation of the sparingly soluble sodium hypophosphite; **sodium sulphate** behaves similarly. A white precipitate is quickly produced on adding **sodium acetate** to the acid. The blue precipitate produced by **copper sulphate** does not change its colour when boiled. The white precipitate produced by **silver nitrate** is not discoloured by boiling, and unlike the corresponding precipitates with phosphorous and hypophosphorous acid, does not blacken on exposure to light; gold chloride is not reduced. White precipitates are produced with **lime-water,** and **baryta-water**; while **calcium and barium chlorides** do not give a precipitate. With a soln. of **magnesium sulphate**, a precipitate is produced when ammonia is added—the precipitate dissolves when ammonium chloride is added. A precipitate is produced with **zinc sulphate** when ammonia is added, and the precipitate is soluble in an excess of ammonia. A soln. of **mercuric chloride** gives no precipitate and is not reduced; but, added L. Amat, if the soln. is warmed, mercurous chloride is precipitated, probably because of the splitting of hypophosphoric acid into phosphorous and phosphoric acids. T. Salzer found that soln. of *mercurous and mercuric nitrates* give white precipitates which do not change in colour in boiling soln. A soln. of **potash-alum** behaves like zinc sulphate. A soln. of *lead nitrate* or *lead acetate* gives a white precipitate. A soln. of **potassium dichromate** is not reduced even by boiling hypophosphoric acid. N. Parravano and C. Marini found that complex salts are produced by **molybdates** and **tungstates**, but the salts were not isolated; T. Salzer found that a mixture of ammonium molybdate and hydrochloric acid gives no precipitate in cold or hot soln., but when the hot soln. is mixed with nitric acid, the yellow precipitate characteristic of the phosphates is formed. A soln. of a **permanganate** is slowly reduced in the cold and rapidly when heated in the presence of dil. sulphuric acid. A soln. of **ferrous sulphate** gives a small precipitate; and a soln. of **ferric chloride,** a copious white precipitate. A soln. of **platinic chloride** gives no precipitate and is not reduced by hypophosphoric acid.

§ 22. The Hypophosphates

In 1877 and subsequent years, T. Salzer[1] prepared the primary, secondary, tertiary, and quaternary salts as well as some more complex types. Some of the hypophosphates are obtained by saturating the acid with the base, and others by double decomposition of, say, the barium salt with a sulphate of the required base. The alkali salts are usually soluble in water, while the secondary sodium salt, the barium, and the silver salts, and the salts of the heavy metals are but sparingly soluble in water. The salts, in general, behave like the phosphites and hypophosphites, but they are much more stable, and require a higher temp. for decomposition. When heated, they usually break down, giving off hydrogen or phosphine, and leaving behind a phosphide or phosphate or a mixture of the two—silver hypophosphate gives silver and the metaphosphate. J. Palm prepared manganese, iron, chromium, aluminium, acid bismuth hypophosphates in a similar way. P. Drawe, J. Palm, and C. Bansa prepared isomorphous, rhombic crystals of the acidic double salts of the type $M''H_2P_2O_6.K_2H_2P_2O_6.nH_2O$, where M″ denotes an atom of a bivalent metal—nickel, cobalt, cadmium, manganese, zinc, and copper—also normal double salts $M''K_2P_2O_6.nH_2O$, where M″ denotes an atom of bivalent cobalt or nickel. Double salts with sodium in the place of potassium were also obtained.

A. Sänger prepared *ethyl hypophosphate*, $(C_2H_5)_4P_2O_6$, as a thick, colourless liquid of sp. gr. 1·117 at 15°, by heating silver hypophosphate with ethyl iodide. The ester is hydrolyzed by water, and decomposes, when heated, into ethyl phosphate and phosphite. Consequently, the vapour density cannot be determined. The corresponding *methyl hypophosphate*, $(CH_3)_4P_2O_6$, has a sp. gr. 1·109 at 15°. Both esters form a calcium salt, $RCaHP_2P_6.5H_2O$. A. Rosenheim, W. Stadler and F. Jacobsohn could not prepare ethyl hypophosphate because it so readily passed into ethyl pyrophosphate. A. Rosenheim and J. Pinsker also prepared white needle-like crystals of a characteristic sparingly soluble *guanidine hypophosphate*, $(CN_3H_5)_4H_2PO_3.5H_2O$, by treating guanidine carbonate with a soluble hypophosphate or the free acid; and I. Müller showed that if hot conc. soln. are mixed, the precipitated salt has the composition $(CN_3H_5)_2PO_3.H_2O$.

T. Salzer prepared normal or quaternary **ammonium hypophosphate,** $(NH_4)_4P_2O_6.H_2O$, by treating a 5 per cent. soln. of hypophosphoric acid with an excess of ammonia. The prismatic crystals effloresce so quickly by the loss of ammonia in air that measurements of the crystallographic constants were not practicable. 100 grms. of water dissolve 3·3 grms. of the salt. The aq. soln. has a strong alkaline reaction; it gives no precipitate with ammonia; it loses ammonia when evaporated and becomes acid, furnishing the secondary salt. T. Salzer obtained the secondary salt **ammonium dihydrohypophosphite,** $(NH_4)_2H_2P_2O_6$, by over-saturating the acid with aq. ammonia, and allowing the soln. to evaporate spontaneously. If the soln. is such that no more ammonia escapes during evaporation, some primary salt may be formed. A. P. Sabanéeff evaporated the soln. obtained by neutralizing the free acid with ammonia, using methyl-orange as indicator; and T. Salzer, the soln. obtained by the double decomposition of the secondary barium salt with ammonium sulphate. The granular or acicular crystals lose neither water nor ammonia at 110°; and the salt can be heated to 160° for an hour without appreciable decomposition, but at a higher temp., decomposition occurs. A. P. Sabanéeff gave 170° for the m.p., and found the mol. wt. by cryoscopic observations of the aq. soln. in agreement with the formula indicated, so that the salt is structurally isomeric with hydrazine hydrophosphite. T. Salzer found that 100 grms. of water at 14° dissolve 7·1 grms. of salt, and at the boiling temp., 25 grms. If a soln. of this salt with the necessary quantity of acid be evaporated on a water-bath, and allowed to crystallize in a desiccator, granular crystals of the primary salt, **ammonium trihydrohypophosphate,** $(NH_4)H_3P_2O_7$, are formed. This salt is very soluble in water; it melts at a lower temp. than the dihydro-salt, but otherwise behaves in a similar way.

A. P. Sabanéeff prepared **hydroxylamine dihydrohypophosphate,** $(NH_3OH)_2H_2P_2O_6$, by crystallization from a soln. obtained by mixing the barium salt with hydroxylamine hydrosulphate. The salt is structurally isomeric with hydrazine dihydrophosphate; it melts with decomposition at 139°; and is freely soluble in water. He prepared **hydrazine dihydrohypophosphate,** $(N_2H_5)_2H_2P_2O_6$, by crystallization from a soln. of the acid neutralized with hydrazine hydrate using methyl-orange as indicator. The prismatic crystals are freely soluble in water. If half of a given amount of hypophosphoric acid be neutralized as just indicated, and mixed with the other portion of acid, the soln. furnishes crystals of **hydrazine trihydrohypophosphate,** $(N_2H_5)H_3P_2O_6$. The salt is structurally isomeric with ammonium dimetaphosphate; it melts at 152°; and, at ordinary temp., 100 grms. of water dissolve 1·5 grms. of the salt. If the aq. soln. of this salt be neutralized with ammonia, using methyl-orange as indicator, and the soln. allowed to crystallize without warming, **hydrazine ammonium dihydrohypophosphate,** $(NH_4)(N_2H_5)H_2P_2O_6$, is obtained in small crystals, readily soluble in water.

According to C. F. Rammelsberg, and T. Salzer normal **lithium hypophosphate,** $Li_4P_2O_6.7H_2O$, is obtained by mixing soln. of the normal sodium salt and lithium chloride in the molar proportions 1 : 2 ; and by adding sufficient lithium carbonate to hypophosphoric acid to give a liquid which still has an acid reaction. H. Schuh regarded this salt as a hexahydrate. A. Rosenheim and W. Reglin gave for the sp. conductivity of a sat. soln. at 25°, $2{\cdot}772\times10^{-4}$ mho. C. F. Rammelsberg said that the salt can be recrystallized from a hot conc. soln. in water and acetic acid. The crystals lose 5 mols of water at 120°, and 6 mols at 300°. The salt is sparingly soluble in water—C. F. Rammelsberg said that at ordinary temp. 100 grms. of water dissolve 0·83 grm. of the salt. A. Rosenheim and W. Reglin observed a negative temp. coeff. of the solubility, for at 0°, 25°, and 40°, 100 grms. of a sat. soln. contained respectively 0·1018, 0·0575, and 0·0480 grm. of $Li_4P_2O_6.7H_2O$. The salt is easily soluble in hypophosphoric acid. The mother-liquor from the normal salt yields ill-defined crystals of **lithium dihydrohypophosphate,** $Li_2H_2P_2O_6.2H_2O$. H. Schuh regarded it as a tetrahydrate. I. Müller has investigated the conditions of equilibrium of the ternary system, $Na_2O{-}P_2O_4{-}H_2O$, at 30°, and his numbers are plotted in Fig. 38. The point *A* corresponds with a sat. soln. of $NaHPO_3.3H_2O$, or $Na_2H_2P_2O_6.6H_2O$, and the curve *AB* must correspond with the appearance of a second salt, otherwise the addition of soda-lye to a sat. soln. of $NaHPO_3.3H_2O$ would lower the solubility. This salt is T. Salzer's $Na_3HP_2O_6.9H_2O$, or $Na_3H(PO_3)_2.9H_2O$; *B* represents the solubility of a sat. soln. of this salt. The behaviour of the curve *BCD* (allowing for errors of experiment) corresponds with the formation of T. Salzer's $Na_5H_3(P_2O_6)_2.20H_2O$, but the salt was not isolated. The curve *DE* corresponds with the appearance of needle-like crystals of the salt $Na_2PO_3.5H_2O$, or T. Salzer's $Na_4P_2O_6.10H_2O$. The kink *H* in the curve *AG* corresponds with the salt $Na_3H_5(P_2O_6)_2.nH_2O$—the sodium analogue of T. Salzer's $K_3H_5(P_2O_6)_2.2H_2O$—but the salt was not isolated. Under the conditions of these experiments, therefore, four salts—$Na_4P_2O_6.10H_2O$; $Na_3HP_2O_6.9H_2O$; $Na_2H_2P_2O_6.6H_2O$; and $NaH_3P_2O_6.2H_2O$—can exist in aq. soln. at 30° ; while the salts, $Na_5H_3(P_2O_6)_2.20H_2O$, and $Na_3H_5(P_2O_6)_2.nH_2O$, could not be obtained, though there were indications of their presence.

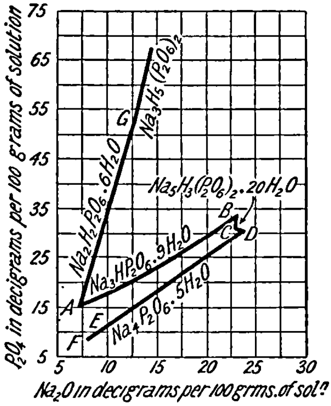

FIG. 38.—Equilibrium in the Ternary System: $Na_2O{-}P_2O_4{-}H_2O$.

T. Salzer, C. F. Rammelsberg, and H. Schuh prepared acicular crystals of the decahydrated normal **sodium hypophosphate,** $Na_4P_2O_6.10H_2O$, by cooling a boiling soln. of equimolar parts of sodium dihydrohypophosphate and sodium carbonate; if an excess of conc. soda-lye be rapidly added to a soln. of one part of the dihydro-salt in 50 parts of water, the salt is immediately precipitated, if the soda-lye be not in excess, the soln. remains clear, and the crystals are deposited by gradually adding more lye. The range of stability is indicated in Fig. 38. The six-sided monoclinic crystals were found by W. Fresenius to have the axial ratios $a:b:c$ $=2{\cdot}0435:1:1{\cdot}9099$; while H. Dufet gave $1{\cdot}1718:1:1{\cdot}9077$, and $\beta=79°\ 44'$, and sp. gr. 1·8233. T. Salzer found that when the salt is heated, it decomposes without incandescence, forming a reddish-coloured mass, which gives a turbid yellowish-red soln. in water. If the tetrasodium salt is heated, it passes into the pyrophosphate, while the disodium salt forms the metaphosphate—it is therefore possible to determine the proportions of the di- and tetra- sodium hypophosphates in a mixture of the two on the assumption that each constituent of the mixture behaves like it would alone. 100 parts of water dissolve 2 parts of the salt. I. Müller gave for the solubility of the anhydrous salt in 100 grms. of water:

	25·2°	30°	35°	40·2°	45°	50°
Solubility .	1·49	1·72	1·96	2·27	2·71	3·18 grms.

T. Salzer found that the aq. soln. reacts alkaline, and colours turmeric brown, and, said A. Joly, phenolphthalein, red. T. Salzer added that the salt cannot be recrystallized from water without change. Bromine changes the aq. soln. into the dihydropyrophosphate: $Na_4P_2O_6+Br_2+H_2O=Na_2H_2P_2O_7+2NaBr$. T. Salzer said that in preparing the normal salt, sometimes a small quantity of a salt of the same composition is formed; it is almost insoluble in water. It has not been examined, and was provisionally regarded as a polymer. If a mol of sodium carbonate, and 4 mols of the dihydro-salt, be dissolved in water and boiled until carbon dioxide is no longer evolved, rhombic plates of **sodium trihydrodihypophosphate,** $Na_5H_3(P_2O_6)_2.20H_2O$, separate on cooling. The range of stability is indicated in Fig. 38. K. Haushofer said that the monoclinic crystals have the axial ratios $a:b:c=1·3638:1:0·5761$, and $\beta=78° 38'$. T. Salzer added that 100 parts of water dissolve 6·7 parts of the salt; the soln. is only feebly acid; and on evaporation furnishes crystals of the dihydro- and trihydro-salts. I. Müller suspected the existence of **sodium pentahydrodihypophosphate,** $Na_3H_5(P_2O_6)_2$, with the very limited range of stability indicated in Fig. 38.

T. Salzer prepared **sodium hydrohypophosphate,** $Na_3HP_2O_6.9H_2O$, from a soln. of a mol of the dihydro-salt with 0·5 mol of sodium carbonate, or a mol of the normal salt. The range of stability is indicated in Fig. 38. The clear, colourless crystals are usually tabular, and, according to H. Dufet, belong to the monoclinic system, having the axial ratios $a:b:c=1·5592:1:1·5108$; $\beta=77° 33'$; and the sp. gr. 1·7427. T. Salzer added that the salt loses its water of crystallization at 100°, and at a higher temp. glows and gives off phosphine. The crystals do not effloresce in air; 100 parts of water dissolve 4·5 parts of salt. According to I. Müller, 100 grms. of water dissolve *S* grms. of the anhydrous salt:

	25°	30·2°	35·2°	40°	45°	50°
Solubility .	4·67	5·88	7·16	9·00	11·85	14·96 grms.

T. Salzer said that the aq. soln. is alkaline, and, according to A. Joly, gives a pale violet colour with phenolphthalein. T. Salzer, and H. Schuh prepared **sodium dihydrohypophosphate,** $Na_2H_2P_2O_6.6H_2O$, from hypophosphoric acid as previously indicated in connection with the acid. The range of stability is indicated in Fig. 38. A. Joly obtained it from a soln. of hypophosphoric acid neutralized with sodium carbonate until a methyl-orange indicator reddens. The monoclinic crystals are often monoclinic. K. Haushofer gave for the axial ratios $a:b:c=2·0052:1:2·0568$, and $\beta=52° 33'$; while C. R. Fresenius gave $a:b:c=2·0115:1:2·0438$, and $\beta=53° 10·5'$. H. Dufet added that the birefringence is positive, and the sp. gr. 1·8491. According to T. Salzer, the clear crystals remain unchanged at ordinary temp., but over conc. sulphuric acid, or in contact with alcohol, they lose water and become turbid. At 100°, the water of crystallization is expelled, and the salt suffers no further change at 200°, but at 250° the salt melts, and at higher temp. gives off phosphine and hydrogen, and forms sodium phosphide as well. When heated in an atm. of carbon dioxide, no phosphine is given off. 100 grms. of cold water dissolve 2·2 grms. of the salt, and boiling water, 20 grms. I. Müller gave for the solubility of the dihydro-salt in 100 grms. of water:

	25°	30°	35°	40°	45°	50°
Solubility . .	2·00	2·57	3·08	3·77	4·76	5·95

The results are indicated in Fig. 36. According to T. Salzer, the aq. soln. has an acid reaction, and is stable in air; the salt dissolves more easily in dil. sulphuric acid than in water; it is freely soluble in aq. ammonia; and not so soluble in a soln. of sodium carbonate. N. Parravano and C. Marini, and A. Rosenheim and W. Stadler measured the electrical conductivity of soln. of the sodium salts; A. Rosenheim and W. Reglin gave for the eq. conductivity, λ, with a mol of the salt, $Na_2H_2P_2O_6.6H_2O$, in v litres of water at 25°:

v	8	16	32	64	128	256	512	1024
λ	71·8	78·8	86·1	92·2	95·9	98·1	100·7	101·6

T. Salzer prepared **sodium trihydrohypophosphate,** $NaH_3P_2O_6$, by slowly cooling a hot conc. soln. of the dihydro-salt mixed with some hypophosphorous acid. I. Müller also obtained this salt. According to K. Haushofer, the acicular or tabular crystals are monoclinic with the axial ratios $a:b:c=2·0023:1:1·0907$, and $\beta=82° 41'$. The aq. soln. deposits crystals of the dihydro-salt. When heated, the salt melts in its water of crystallization, and at a higher temp., the salt decrepitates and gives off hydrogen which ignites.

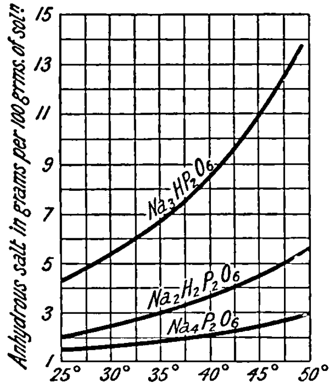

FIG. 39.—The Solubility of the Sodium Hypophosphates in Water.

T. Salzer prepared primary or normal **potassium hypophosphate,** $K_4P_2O_6.8H_2O$, by adding 2 mols of potassium hydroxide to a soln. containing one mol of the dihydro-salt, and evaporating to a syrupy liquid on the water-bath, and finally in a desiccator. C. Bansa said that the salt cannot be prepared by double decomposition of the barium salt with potassium sulphate because the reaction is an incomplete one. K. Haushofer said that the prismatic or tabular crystals are rhombic pyramids with a tetragonal habit, and have the axial ratios $a:b:c=0·9458:1:1·0124$. T. Salzer found that 100 grms. of water dissolve rather more than 25 grms. of the salt. The soln. is alkaline, and does not absorb carbon dioxide from the air. The salt melts at about 40° in its water of crystallization; it loses three-quarters of its water at 60°, and the remainder at 150° without decomposition; but at a higher temp. it forms pyrophosphate. The salt is insoluble in alcohol, but is not precipitated by alcohol from its aq. soln. T. Salzer also found that **potassium pentahydrodihypophosphate,** $K_3H_5(P_2O_6)_2.2H_2O$, is deposited when a soln. containing 3 mols of potassium dihypophosphate and one mol of hypophosphoric acid is evaporated. If a smaller proportion of acid is used, this salt is also formed, but is apt to contain potassium trihydrohypophosphate. According to C. R. Fresenius, and K. Haushofer, the crystals belong to the rhombic system, and have the axial ratios $a:b:c=0·6792:1:0·8508$. The salt is soluble in 2·5 parts of cold and in 0·8 part of boiling water. On the addition of alcohol to the aq. soln., dipotassium hypophosphate is precipitated. The crystals become anhydrous at 100°.

T. Salzer obtained **potassium hydrohypophosphate,** $K_3HP_2O_6.3H_2O$, by the addition of equimolar parts of potassium hydroxide to a soln. of potassium dihypophosphate and evaporating for crystallization. According to K. Haushofer, the salt crystallizes in the monoclinic system, and has the axial ratios $a:b:c=0·4224:1:0·9902$, $\beta=89° 35'$. T. Salzer said that the crystals are soluble in half their weight of water, forming an alkaline soln., but are insoluble in alcohol. They lose their water of crystallization at 100°, and at a higher temp. form potassium pyro- and meta-phosphate. T. Salzer also prepared di- and tri-hydrated **potassium dihydrohypophosphates,** $K_2H_2P_2O_6.2H_2O$, and $K_2H_2P_2O_6.3H_2O$, from the soln. obtained by digesting the barium salt with a soln. of potassium sulphate. The evaporation of the filtered soln. furnishes either rhombic prisms or plates of the trihydrate which, according to K. Haushofer, have the axial ratios $a:b:c=0·9873:1;0·9190$; or monoclinic plates of the dihydrate, having the axial ratios $a:b:c=0\cdot7241:1:0\cdot7949$, and $\beta=87°\ 50'$. T. Salzer did not find a method for obtaining crystals of only one form. The trihydrate effloresces in air, the dihydrate is stable. They lose their water of crystallization at 100°, and at a higher temp. give off hydrogen which inflames; the residue contains the metaphosphate. Both salts dissolve in three times their weight of cold water, and in their own weight of hot water. They are precipitated from their aq. soln. by the addition of alcohol. These two alleged hydrates want further examination. According to T. Salzer, **potassium trihydrohypophosphate,** $KH_3P_2O_6$, is deposited during the slow cooling of a hot conc. soln. of the dihydro-salt and hypophosphoric acid. The monoclinic prisms were found by K. Haushofer to have the axial ratios $a:b:c=0\cdot9331:1:0\cdot6612$, and $\beta=43°\ 7'$. T. Salzer added that 100 parts of water dissolve 66·7 parts of salt in the cold, and when boiling, 200 parts of salt. The soln., which have an acid reaction, give a precipitate with alcohol. On spontaneous evaporation, the cold aqueous soln. yields potassium pentahydrodihypophosphate; whilst the hot soln. contains, in addition to this salt, the potassium hydrohypophosphate. The trihydrohypophosphate undergoes no change at 100°, but at 120° it absorbs moisture from the air, forming phosphorous acid and potassium pyrophosphate.

The two series of potassium and sodium salts prepared by T. Salzer are thus analogous, but he could not make the sodium analogue of $K_3H_5(P_2O_6)_2.2H_2O$, nor the potassium analogue of $Na_5H_3(P_2O_6)_2.20H_2O$. There is no evidence to show that the sodium salt, $Na_5H_3(P_2O_6)_2.20H_2O$, and the potassium salt, $K_3H_5(P_2O_6)_2.2H_2O$, are derivatives of polymerized hypophosphoric acid; they may be association products analogous with H.COOH.H.COONa; $KNO_3.2HNO_3$; etc. If the mol. constitution of the acid be H_2PO_3, this would render necessary a modification of the present view of the constitution of these salts. The quaternary sodium salt would become $Na_2PO_3.5H_2O$; and the secondary salt, $NaHPO_3.3H_2O$; while the tertiary salt, $Na_3HP_2O_6.9H_2O$, would become a double salt, $Na_2PO_3.NaHPO_3.9H_2O$; the primary salt, $NaH_3P_2O_6.2H_2O$; a double salt, $H_2PO_3.NaHPO_3.2H_2O$; and the pentasodium salt, a double salt, $Na_2PO_3.3NaHPO_3.20H_2O$. H. Schuh prepared **rubidium dihydrohypophosphate,** $Rb_2H_2P_2O_6.2H_2O$; and the normal **rubidium hypophosphate,** $Rb_4P_2O_6.10H_2O$.

T. Salzer obtained a blue precipitate on adding a soln. of cupric sulphate to hypophosphoric acid, and P. Drawe prepared **cupric hypophosphite,** $Cu_2P_2O_6.6H_2O$, by adding a warm dil. soln. of the normal salt to an excess of warm soln. of copper sulphate. The salt is insoluble in water, and soluble in dil. acids. It does not form the pyrophosphate when calcined in air. C. Bansa made **potassium copper octohydrotetrahypophosphate,** $3K_2H_2P_2O_6.CuH_2P_2O_6.15H_2O$, or $K_6CuH_8(P_2O_6)_4.15H_2O$, by adding to a conc. soln. of potassium dihydrohypophosphate a few drops of a 20 per cent. soln. of cupric sulphate. On standing a few hours, the soln. deposits pale blue, acicular, and tabular crystals of the complex salt, which melts with decomposition at 170°. T. Salzer prepared **silver hypophosphate,** $Ag_4P_2O_6$, by the action of silver nitrate on a neutral or acidic soln. of sodium hypophosphate; J. Philipp, by warming phosphorus with dil. nitric acid in the presence of silver nitrate—*vide supra*; A. Sänger, by the action of silver nitrate in neutral or feebly ammoniacal soln. on sodium hypophosphate—some silver suboxide is formed at the same time—*vide supra*; and F. Tauchert, by the action of silver nitrate on a warm soln. of sodium dihydrohypophosphate. The white salt is not very sensitive to light; and when boiled with its mother-liquor, is not discoloured. It is insoluble in water, and sparingly soluble in nitric acid; and almost insoluble in hypophosphoric acid, so that T. Salzer was unable to make an acidic salt. J. Philipp said that the salt can be recrystallized from a nitric acid soln. of silver nitrate; and A. Sänger, that the salt is oxidized to the normal phosphate by silver oxide. C. Bansa obtained crystals of **sodium potassium hypophosphate,** $Na_2K_2P_2O_6.9H_2O$, by adding the theoretical quantity of potassium carbonate to a soln. of sodium dihydrohypophosphate. The rhombic crystals have the axial ratios $a:b:c$

=1·0728 : 1 : 1·00845. The crystals do not change in air. They are soluble in about 3 parts of hot water, or 25 parts of cold water; 8 mols of water are lost at 100°, and the remainder at 260°; at 300°, the salt becomes brown, then white again, and finally melts. At a red-heat, the salt burns owing to the inflammation of the escaping hydrogen. No phosphine was detected.

T. Salzer made normal **calcium hypophosphate,** $Ca_2P_2O_6.2H_2O$, by treating a soln. of the normal sodium salt with calcium chloride. He added that a neutral soln. of a calcium salt will give a turbidity with a dilution of 1 in 20,000. The washed precipitate is not crystalline, but gelatinous, and it becomes granular after standing some time. The air-dried salt retains some moisture. The combined water is lost at 200° when some oxidation occurs. At a dull red-heat, calcium pyrophosphate is formed without the inflammation of evolved hydrogen. The salt is insoluble in water; sparingly soluble in acetic acid; and freely soluble in hydrochloric or hypophosphoric acid. If barium dihydrohypophosphate suspended in water is treated with calcium sulphate, or the normal calcium salt be treated with the theoretical quantity of hypophosphoric acid, and the clear soln. evaporated without a rise of temp., crystals of **calcium dihydrohypophosphate,** $CaH_2P_2O_6.6H_2O$, are formed. According to K. Haushofer, the monoclinic plates or prisms have the axial ratios $a:b:c=1·1342:1:2·5426$, and $\beta=94°\ 31'$. T. Salzer found that the salt loses two-thirds of its water on exposure to air, and the remainder at 150°. There is a partial decomposition of the salt at that temp. When rapidly heated the salt decomposes and the liberated hydrogen burns with a blue flame. 100 parts of water dissolve 1·7 parts of salt. H. Schuh prepared normal **strontium hypophosphate,** $Sr_2P_2O_6.2H_2O$; and **strontium dihydrohypophosphate,** $SrH_2P_2O_6.3H_2O$. T. Salzer, C. Bansa, and H. Schuh prepared normal **barium hypophosphate,** $Ba_2P_2O_6$, by treating a soln. of the normal sodium salt with barium chloride. At a red-heat, the white, pulverulent mass passes into the pyrophosphate without incandescence. C. F. Rammelsberg said that the salt dried over sulphuric acid retains 1·6 per cent. of moisture. H. E. Quantin said that the salt is decomposed by the vapour of carbon tetrachloride at a red-heat, forming barium chloride, carbonyl chloride, and carbon dioxide. T. Salzer made **barium dihydrohypophosphate,** $Ba_2H_2P_2O_6.2H_2O$, by dissolving the normal salt in the theoretical quantity of hypophosphoric acid, and evaporating for crystallization without raising the temp.; also by precipitation on mixing a soln. of 12 grms. of dihydrated barium chloride in 120 grms. of water and a soln. of 16 grms. of hexahydrated sodium dihydrohypophosphate in 100 grms. of water, and 6 c.c. of hydrochloric acid of sp. gr. 1·124. According to A. Joly, if a nearly boiling soln. of hypophosphoric acid is treated with one-quarter the amount of barium carbonate required for neutralization, on cooling, the dihydro-salt is precipitated free from phosphite and phosphate. C. F. Rammelsberg obtained the salt by evaporating a soln. of the normal salt in hydrochloric acid. The clear, needle-like crystals were found by W. Fresenius to belong to the monoclinic system, and to have the axial ratio $a:b:c=1·8480:1:$—, and $\beta=122°\ 56'$. The slimy precipitate of the barium salt, said A. Joly, is formed with thermal change, but when this passes into the crystalline salt, 4·76 Cals. are evolved. The heat of neutralization of barium hydroxide and hypophosphoric acid is 56·4 Cals. when barium dihydrohypophosphate is formed. T. Salzer said that the crystals suffer no appreciable change at 100°; at 140°, they lose their water of crystallization, and at a higher temp. hydrogen is evolved, and this inflames. Barium metaphosphate remains. When the clear crystals are heated under water, they become opaque, and the water becomes acid owing to the formation of a small quantity of the normal salt.

C. F. Rammelsberg, and J. Palm prepared crystals of normal **beryllium hypophosphate,** $Be_2P_2O_6.3H_2O$, by mixing a cold soln. of the normal sodium salt with beryllium sulphate. The pulverulent mass loses about half its water of crystallization at 230°–250°. T. Salzer made normal dodecahydrated **magnesium hypophosphate,** $Mg_2P_2O_6.12H_2O$, by mixing a cold soln. of the normal sodium salt

(1 : 100) with the theoretical quantity of magnesium sulphate—the precipitate is crystalline. If hot soln. are mixed, the precipitate is gelatinous, and crystallization then occurs only after long standing. The precipitate is washed free from sulphates. The microcrystalline, rhombic or hexagonal plates are stable in air; they lose five-sixths of their water at 110°; and at 170°, more water is given off with some decomposition of the salt. 100 parts of water dissolve 0·0067 part of salt. C. F. Rammelsberg also examined this salt, and found that if the soln. in acetic acid with a drop of hydrochloric acid be evaporated, crystals of the *tetracosihydrate* are formed which lose 12 mols of water at 200°. T. Salzer made **magnesium dihydrohypophosphate,** $MgH_2P_2O_6.4H_2O$, by digesting the barium salt with a soln. of magnesium sulphate; or by digesting a mol of the normal salt with a mol of hypophosphoric acid. The dil. soln. can be boiled without change, and crystals of the salt are obtained by evaporating the liquid. The crystals are stable in air; they lose water of crystallization at 150°; and decompose with a glow at a higher temp. 100 parts of water dissolve 0·5 part of salt—*vide supra,* the action of the acid on magnesium salts. P. Drawe prepared **zinc hypophosphate,** $Zn_2P_2O_6.2H_2O$, by stirring an excess of a dil. soln. of zinc sulphate with one of sodium dihydrohypophosphate, and after 24 hrs. filtering the soln., washing with hot water, and drying on porous tiles. The white powder at 110° becomes yellow, and at a higher temp., glows. The white product suffers a loss of 8·9 per cent. in weight. C. Bansa prepared **potassium zinc octohydrotetrahypophosphate,** $3K_2H_2P_2O_6.ZnH_2P_2O_6.15H_2O$, by mixing a few drops of a conc. soln. of zinc sulphate to one of potassium dihydrohypophosphate (1 : 3) at ordinary temp. The crystalline precipitate loses all its water after heating 4 hrs. at 100°; and melts with decomposition at 140°. P. Drawe prepared **cadmium hypophosphate,** $Cd_2P_2O_6.2H_2O$, by the method employed for the zinc salt. The product is insoluble in water, and alcohol, but freely soluble in dil. acids. The salt loses half its water of crystallization at 100°, and at 110°, it loses in weight and becomes superficially yellow. It decomposes when ignited, forming the metal phosphide. He also prepared **potassium cadmium tetrahydrodihypophosphate,** $K_2H_2P_2O_6.CdH_2P_2O_6.2\frac{1}{2}H_2O$, in rhombic crystals, by a method analogous to that employed for the zinc salt. The salt begins to lose water at 120°, but is not completely dehydrated at a red-heat. It melts at 170°. No **mercury hypophosphate** has been made; according to L. Amat, mercuric chloride oxidizes hypophosphoric acid quantitatively into phosphoric acid; and is itself reduced to mercurous chloride—*vide supra,* hypophosphorous acid.

J. Palm prepared **aluminium hypophosphate** from a soln. of the normal sodium salt and aluminium sulphate. C. F. Rammelsberg reported normal **thallous hypophosphate,** $Tl_4P_2O_6$, to be formed by neutralizing a soln. of the acid with thallous carbonate; and A. Joly, by double decomposition with thallous sulphate and a hot aq. soln. of the normal sodium salt. The colourless needles are sparingly soluble in water. A. Joly said that in direct sunlight, the salt is coloured indigo-blue; and it remains unchanged when heated to 210°, but, added A. Joly, it melts and decomposes: $Tl_4P_2O_6=2TlPO_3+2Tl$, at 250°. A. Joly made **thallous dihydrohypophosphate,** $Tl_2H_2P_2O_6$, by neutralizing a soln. of the acid with thallous carbonate, using methyl-orange as indicator, or mixing barium dihydrohypophosphate and thallous sulphate in boiling aq. soln. H. Dufet said that the monoclinic crystals have the axial ratios $a:b:c=0{\cdot}9089:1;\ 1{\cdot}2975$, and $\beta=94°\ 50'$. A. Joly said that the salt melts at 200° and forms a phosphite without the evolution of a gas. C. F. Rammelsberg reported small, colourless crystals of **thallous hydrohypophosphate,** $Tl_4P_2O_6.Tl_2H_2P_2O_6$, or $Tl_3HP_2O_6$, to be formed by mixing the soln. of hypophosphoric acid neutralized with thallous carbonate with the theoretical amount of acid, and evaporating the clear soln. O. Hauser and H. Herzfeld prepared **zirconium hypophosphate,** $ZrP_2O_6.H_2O$, by warming a soln. of zirconium nitrate in dil. hydrochloric acid with an excess of sodium hypophosphate. T. Salzer reported **lead hypophosphate,** $Pb_2P_2O_6$, to be formed by treating sodium dihydrohypophosphate with a large excess of lead nitrate, acetate, or basic acetate. H. Schuh, and F. Tauchert employed a similar process. The white, pulverulent mass is not altered at 120°, at a higher temp. it blackens, and may glow if in a thin layer; and if air has access: $Pb_2P_2O_6+O=Pb_2P_2O_7$. It is insoluble in water, dil. acetic acid, and hypophosphoric acid; but it is soluble in dil. nitric acid. It is readily decomposed by dil. sulphuric acid. O. Kauffmann prepared **thorium hypophosphate,** $ThP_2O_6.11H_2O$, by precipitation from a soln. of thorium nitrate as in the case of the zirconium salt. It is also obtained by adding hypophosphoric acid to a soln. of thorium nitrate. The white, pulverulent mass loses its water of crystallization at 160°–170°. O. Kauffmann said that it is insoluble in water, dil. acids, and alkalies, and in conc. acids, but V. I. Spitzin found N-H_2SO_4 dissolves 53 mgrms. per litre; N-HCl, 24 mgrms. per litre; N-HNO_3, 12 mgrms. per litre; and N-K_2CO_3, 250 mgrms. per litre. O. Kauffmann said that it is opened up by fusion with sodium hydrosulphate, and dissolution by hydrochloric acid.

J. Palm reported **bismuth hypophosphate** to be formed from a soln. of the normal sodium salt and bismuth nitrate. J. Palm prepared **chromium hypophosphate** from a soln. of the normal sodium hypophosphate and a chromium salt. According to N. Parravano and C. Marini, sodium hypophosphate forms complex anions with molybdic acid, represented by **sodium hypophosphatomolybdate:** $2Na_2MoO_4+H_4P_2O_6=2H_2O+Na_4P_2O_6.2MoO_3$, and I. Müller prepared the complex molybdenum salt by treating a boiling soln. of sodium hypophosphite with an excess of molybdic trioxide, MoO_3, and treating the clear greenish soln. with bromine water—pale yellow crystals of sodium hypophosphatomolybdate, $Na_2[P(Mo_2O_7)].8H_2O$, appear. N. Parravano and C. Marini also obtained evidence of the formation of a complex **sodium hypophosphatotungstate.** They measured the electrical conductivities of hypophosphatomolybdates. J. Palm reported **manganese hypophosphite** to be formed from a soln. of the normal sodium salt and manganese chloride; and C. Bansa obtained colourless, rhombic crystals of **potassium manganese tetrahydrodihypophosphate,** $MnH_2P_2O_6.K_2H_2P_2O_6.3H_2O$, as in the case of the cadmium salt. J. Palm prepared **iron hypophosphate** as in the case of the manganese salt. P. Drawe prepared **cobalt hypophosphate,** $Co_2P_2O_6.8H_2O$, by mixing a warm dil. soln. of the normal sodium salt with an excess of a warm soln. of cobalt sulphate. The salt is almost insoluble in water, and when heated, it readily oxidizes. S. Bansa made **potassium cobalt hypophosphate,** $K_2CoP_2O_6.5H_2O$, by mixing a soln. of 3 grms. of heptahydrated cobalt sulphate in 20 c.c. of hot water with a hot 5 per cent. soln. of the normal potassium salt. When the rose-coloured mass of crystals is heated, it becomes blue, and finally black. P. Drawe made six-sided plates of **sodium cobalt hypophosphate,** $Na_2CoP_2O_6.1\frac{1}{2}H_2O$, by mixing a dil. soln. of cobalt sulphate with one of the normal sodium salt at 0°. The salt is decomposed by water, forming normal cobalt hypophosphate. The salt loses weight when kept over sulphuric acid, and it becomes dark violet; it also lost 4·3 per cent. of water when kept for 3 hrs. at 110°. At a higher temp., the salt becomes deep blue and finally black. I. Müller prepared brown crystals of **sodium cobaltic hexamminohypophosphate,** $[Co(NH_3)_6]NaP_2O_6.3H_2O$, by mixing hot conc. soln. of cobaltic hexamminotrichloride and sodium hypophosphate. C. Bansa reported **hexapotassium cobalt octohydrotetrahypophosphate,** $3K_2H_2P_2O_6.CoH_2P_2O_6.15H_2O$, or $CoK_6H_8(P_2O_6)_4.15H_2O$, to be formed by mixing a soln. of 7·75 grms. of hexahydrated cobalt ammonium sulphate in 50 c.c. of water with 80 c.c. of a 25 per cent. soln. of potassium dihydrohypophosphate. The pale rose-coloured, rhombic crystals slowly lose water in the desiccator, and become blue. The salt is dehydrated at 100°, and it begins to oxidize at about this temp. The salt becomes black at 200°–300°.

P. Drawe made prismatic crystals of **nickel hypophosphate,** $Ni_2P_2O_6.12H_2O$, by the action of an excess of a warm dil. soln. of the normal sodium salt on a warm soln. of nickel sulphate; C. Bansa also obtained it by the action of potassium dihydrophosphate on an excess of nickel sulphate soln., and mixing the green filtrate with potassium acetate. C. Bansa also obtained **potassium nickel hypophosphate,** $K_2NiP_2O_6.6H_2O$, by mixing a boiling soln. of 3 grms. of hydrated nickel sulphate in 20 c.c. of water on 100 c.c. of a hot soln. of 5 grms. of normal potassium hypophosphate. After heating 6 hrs. at 100°, the salt loses one-third of its water of crystallization and becomes pale yellow; 3 mols. are lost after 9 hrs.' heating, and 4 mols. after 12 hrs.' heating. At a higher temp., a black mass is formed. He also prepared crystals of **hexapotassium nickel octohydrotetrahypophosphate,** $3K_2H_2P_2O_6.NiH_2P_2O_6.15H_2O$, by a method like that employed for the corresponding cobalt salt. The salt loses water when kept over sulphuric acid; all the water of crystallization is expelled at 100°, and the mass becomes yellow—some oxidation also occurs. P. Drawe reported six-sided, hexagonal plates of normal **sodium nickel dihypophosphate,** $Na_4P_2O_6.Ni_2P_2O_6.24H_2O$, to be formed by mixing a dil. soln. of nickel sulphate with an excess of a soln. of normal sodium hypophosphate at 0°. The formula is based on C. Bansa's analysis of the substance prepared by adding sodium acetate to the filtrate obtained from a mixed soln. of nickel sulphate and potassium dihydrohypophosphate.

§ 23. Phosphorus Pentoxide, or Phosphoric Oxide

In 1681, Robert Boyle[1] discovered that when phosphorus is burnt in air or oxygen, white clouds are formed which condense as a voluminous white powder, which was later on termed *fleurs de phosphore*—flowers of phosphorus—by A. S. Marggraf. Observations were also made by J. C. Sturm, S. A. Frobenius, and A. G. Hanckewitz. Analyses by P. L. Dulong, and H. Davy made it clear that flowers of phosphorus is an oxide of that element. These analyses, together with those by A. L. Lavoisier, J. J. Berzelius, T. Thomson, L. J. Thénard, and A. Schrötter, showed that the composition is 43·86 per cent. of phosphorus and 56·32 per cent. of oxygen. The compound is therefore *phosphorus pentoxide*, for the simplest empirical formula is P_2O_5; it is also called *phosphoric oxide*, or *phosphoric anhydride*. The last term is employed because this oxide forms phosphoric acid when treated with water. A. L. Lavoisier knew in 1777 that phosphorus unites with oxygen in different proportions, and G. B. Sage described the preparation of white flakes of a solid by the action of dry air on phosphorus at a low temperature. The product obtained by G. B. le Sage by the combustion of phosphorus in dry air at a low temperature was probably phosphorous oxide, P_2O_3, or a mixture of the oxide with phosphoric oxide, P_2O_5, and phosphorosic oxide.

The preparation of phosphorus pentoxide.—According to H. Davy,[2] phosphoric anhydride is produced in the rapid combustion of phosphorus in the presence of a sufficient quantity of air or oxygen gas. Rapid combustion occurs at 60°, with a yellow flame in air, and a white, dazzling, intensely hot flame in oxygen. Part of the phosphoric oxide rises as a white cloud, which is luminous in the dark, and part remains as a glassy or vitreous mass where the phosphorus burns. The residue usually contains some of the lower oxides. H. Davy, for example, found phosphorus oxide, P_4O_6. As previously indicated, R. Cowper and V. B. Lewes prepared the pentoxide by passing dry air over molten phosphorus, and they noted that, under these conditions, a mixture of phosphorous oxide and crystallized phosphorus remains, and in light the latter passes into the red modification. P. Hautefeuille and A. Perrey found that in this experiment, the crystalline form of phosphoric oxide is deposited on the colder part of the tube, a vitreous variety in the hottest part, and a pulverulent form in between. The vitreous form is said to be obtained by heating either of the other two forms to dull redness; and T. E. Thorpe and A. E. H. Tutton have shown that probably P. Hautefeuille and A. Perrey's crystals were really phosphorus tetroxide, P_2O_4, and that any chemical differences are due to the presence of phosphorous oxide, P_4O_6. The other substances produced in burning phosphorus in air have been previously discussed. R. Threlfall recommended removing phosphorus from the pentoxide by distillation in a stream of purified oxygen over platinized asbestos. W. A. Shenstone and C. R. Beck said that the exposure of platinized asbestos to the vapour of phosphorus pentoxide is very undesirable as the asbestos absorbs the pentoxide very freely, which not only reduces the yield of the purified product, but also would soon remove the platinum from the sphere of action by enveloping it with a coat of the fusible products of the action. They also tried platinized porcelain, but found platinum sponge gave the best results. Roasting the pentoxide in oxygen does not remove the last traces of the lower oxides even if continued for weeks at a temp. not far below the m.p. of the pentoxide. G. I. Finch and co-workers distilled the phosphorus pentoxide in a current of oxygen flowing in a red-hot iron tube. A modification of the process has been described by H. Whitaker. According to W. A. Shenstone and C. R. Beck, phosphorus pentoxide purified by distillation in a current of oxygen is crystalline, but becomes amorphous when suddenly heated. The lower oxides impart a slight garlic-like smell to the product. Phosphorus pentoxide containing these impurities reduces a 10 per cent. soln. of silver nitrate; a boiling soln. of mercuric chloride is also reduced; and on evaporating an aq. soln., there is a faint smell of phosphine and of phosphorus tetroxide. These effects are attributed to the presence of traces of phosphorus tetroxide, P_2O_4, and phosphorous oxide, P_4O_6. E. Jungfleisch said that if dry oxygen acts on dry phosphorus below 18 mm. press., phosphorous oxide, P_2O_3, is formed; and in the cold at ordinary press., phosphoric oxide, P_2O_5, is exclusively formed.

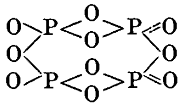
Many different methods for applying the combustion process for the preparation of the pentoxide on a large scale have been devised by J. J. Berzelius,[3] Z. Delalande, R. F. Marchand, A. G. Grabowsky, G. Pistor, T. Goldschmidt, Federal Phosphorus Co., etc. A current of dry air can be aspirated through a large glass balloon, or sheet-iron chamber, while phosphorus is burning in a porcelain dish suspended in the middle of the balloon. Fresh phosphorus is added from time to time through a suitable opening in the upper part of the combustion chamber. The exit tube leads into a wide-mouthed bottle. When sufficient of the product has collected, the bottle is closed by a well-fitting stopper, and replaced by another. A. Schrötter recommended the use of red phosphorus in the combustion process. For the condensation of the "mist" of phosphorus pentoxide, E. Britzke recommended bringing the "mist," in admixture with a large proportion of an inert gas, into intimate contact with active charcoal. As usually prepared by the combustion process, phosphorus pentoxide is a bulky, amorphous powder, but R. Threlfall showed that it can be obtained as a brittle, crystalline mass if condensed at 125°–190°. J. J. Manley removed phosphorous oxide by treatment with ozone.

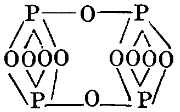
H. Davy,[4] and J. Dalton also found that phosphorus burns vigorously to the pentoxide when it is heated in the vapour of sulphur trioxide, chlorine monoxide, chlorine dioxide, nitrous and nitric oxide, and in nitrogen tri- and per-oxides. He also obtained it by heating phosphorus with conc. sulphuric acid, hypochlorous acid, and chlorous acid and nitric acid. R. F. Marchand found the same oxide is formed by the vigorous and brilliant combustion of phosphorus in molten ammonium nitrate. Phosphorus pentoxide is the end-product of the oxidation when the lower oxides are heated in air—*e.g.* phosphorous oxide (H. Davy), and phosphorus tetritoxide (A. Michaelis and M. Pitsch). The last-named also found that the tritoxide passes into the pentoxide when heated in an indifferent gas: $5P_4O=18P+P_2O_5$. A. Geuther and A. Michaelis obtained phosphorus pentoxide mixed with other products—hydrophosphoryl tetrachloride, phosphoryl chloride, nitrosyl chloride, nitrogen, and a little nitric oxide—as a by-product, during the action of nitrogen trioxide on phosphorus trichloride; and in the distillation of pyrophosphoryl chloride: $P_2O_3Cl_4=POCl_3+PO_2Cl$; and $3PO_2Cl=POCl_3+P_2O_5$; A. Besson made it by the action of a conc. soln. of phosphorous acid on an excess of phosphorus trichloride; G. Oddo, by the action of phosphoryl chloride on potassium chlorate: $2POCl_3+KClO_3=P_2O_5+KCl+3Cl_2$; and C. Mantrand, by heating bone-ash with charcoal in a current of chlorine.

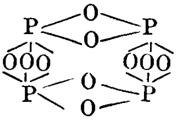
F. S. Brown and C. R. Bury [5] obtained **colloidal solutions** of phosphorus pentoxide in nitrobenzene by stirring the mixture in the presence of alcohols or organic acids. The hydroxy-compound is absorbed and peptizes the pentoxide. Traces of moisture cause coagulation. Conc. soln. set to gels on keeping.

The physical properties of phosphorus pentoxide.—Phosphorus pentoxide is a snow-white pulverulent solid. As indicated above, there are also vitreous and crystalline forms. According to H. Davy,[6] phosphorus pentoxide melts at a red-heat, and sublimes at a higher temp. E. Lautemann sublimed it in a test-tube over a spirit-lamp; and A. Schuller obtained well-defined, water-clear crystals by heating the pentoxide to 50° at one end of a tube cooled by a freezing mixture at the opposite end. The pentoxide can be melted if it be heated quickly. P. Hautefeuille and A. Perrey say that when commercial phosphoric oxide is kept many hours at 150° no other sign of sublimation occurs than a slight deposit in the cold part of the tube; sublimation appears to begin at 210° and is quite fast at 250°, but slower at lower temp. The red portions in the mass of subliming phosphorus pentoxide are supposed by H. Biltz to be the suboxide. The vitreous variety sublimes at a red-heat. R. Kempf found a crystalline sublimate is formed between 180° and 250°; and at 250°, 7·5 grms. sublimed in an hour in vacuo, and 0·38 grm. when the press. was 11 mm. According to A. Grabowsky, T. E. Thorpe and A. E. H. Tutton, and W. A. Tilden and R. E. Barnett, the volatile crystalline form is transformed into the less volatile vitreous form at about 440°. P. Hautefeuille and A. Perrey found the **vapour pressure** of phosphorus pentoxide at 250° to be 760 mm.; and they say that at a temp. a little higher, the crystals polymerize, and the vap. press. falls to a few mm. A. Smits and A. J. Rutgers showed that the vap. press. depends on the velocity of distillation; thus the vap. press. of two different samples were 1·8 atm. and 2·05 atm. at 370. They consider crystalline phosphorus pentoxide to be complex and to contain at least two allotropic forms; it melts over a large range of temp. There is transition point at 400° when the metastable sublimate changes into another form, and the transformation is accompanied by a fall of about 4 atm. in the vap. press. The volatility of the transformed pentoxide is small. The transformed solid has a m.p. of 563° at 0·59 atm. J. M. A. Hoeflake and F. E. C. Scheffer found that the usual crystalline variety has a sublimation point near 360°; between 400° and 500°, the metastable sublimate becomes amorphous and the vap. press. becomes almost zero. The amorphous form becomes a viscid liquid if heated still more and no discontinuity in the vap. press. curve appears.

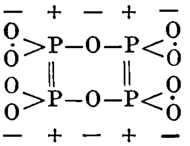
If the viscid liquid be heated a long time at 500°, it forms microscopic needles with a m.p. of 569°. There also appears to be a third form which occurs in tabular crystals, stable above 570°, but metastable in the presence of the acicular crystals. The **vapour density** determined by W. A. Tilden and R. E. Barnett at a red-heat is 336, when the calculated value for P_4O_{10} is 284; C. A. West found 300·4 at 1400° by V. Meyer's process. The simpler formula, P_2O_5, and the name phosphorus pentoxide are employed merely for convenience; actually, we are also ignorant of the mol. wt. of the solid. Several graphic formulæ can be devised for a P_4O_{10}-molecule, on the assumption that the phosphorus atoms are quinquevalent; for example, in agreement with the analyses of J. J. Berzelius,[7] A. L. Lavoiser, V. Rose, T. D. Thomson, H. Davy, P. L. Dulong, and A. Schrötter.







but there is no evidence to decide which of these, if any, is the right one. H. Henstock gave for the electronic structure:



J. Thomsen's value [8] for the **heat of formation** is $2P+5O=P_2O_5+369·9$ Cals. for the solid; and for the dissolved oxide, 405·5 Cals. H. Giran obtained with yellow phosphorus, 369·4 Cals.; with red phosphorus, 362·0 Cals.; and with red phosphorus, 360·0 Cals. Other determinations have been made by M. Berthelot, T. Andrews, J. J. B. Abria, and P. A. Favre and J. T. Silbermann. J. C. Thomlinson argued from the thermochemical data that phosphorus is quadrivalent. The **heat of solution** of the crystalline variety was found by P. Hautefeuille and A. Perrey to be 44·58 Cals.; and 41·32 Cals. for the pulverulent variety; and H. Giran found for the variety obtained by combustion, 34·37 Cals.; for the crystallized variety, 40·79 Cals.; for the amorphous variety, 33·81 Cals.; for the vitreous or glassy variety, 29·09 Cals. P. Hautefeuille and A. Perrey give 3·26 Cals. for the **heat of transformation** of the crystalline into the amorphous variety.

H. Ebert and B. Hoffmann [9] say that strongly illuminated phosphorus pentoxide gives an intense green phosphorescence. The impurities in the commercial product are not the cause of the luminescence; true, there is a pale glow due to the oxidation of the lower oxides present as impurities, but the effect with the highly purified oxide lacks only the oxidation glow. The phosphorescence also occurs in vacuo, and in different dry gases—nitrogen, coal gas, carbon dioxide, carbon monoxide, hydrogen, and helium. The exciting rays are more refrangible than the induced rays. The phosphorescence is intensified by lowering the temp. and the effect is quite brilliant at −180°. W. N. Hartley says that in the oxy-hydrogen blowpipe flame, phosphorus pentoxide gives a continuous **spectrum** with a peculiar line which also occurs in the spectrum of arsenic. H. Ebert and B. Hoffmann say the continuous spectrum has its maximum intensity in the green, and that the pentoxide exhibits a strong **phosphorescence** after illumination, especially at a low temp. F. Zecchini deduced 27·07 for the **molecular refraction** of phosphoric oxide with the μ-formula, and 17·66 with the μ^2-formula—calculated from the value for the salts; and respectively 30·24 and 17·77, from the value for metaphosphoric acid; respectively 34·59 and 19·50 from its value for pyrophosphoric acid; and respectively 29·90 and 17·37 from the value for orthophosphoric acid.

O. W. Richardson found that in the proximity of moist phosphorus pentoxide, a platinum plate charged positively to 80 volts, and at 500°–700°, is discharged, while a cold platinum plate in the vapour of phosphorus pentoxide acquires an electric charge, which it loses in time. Highly purified phosphorus pentoxide does not show the effect.

The chemical properties of phosphorus pentoxide.—E. Rutherford and F. Soddy[10] observed that radium emanation, **niton,** has no action on phosphorus pentoxide. T. E. Thorpe and A. E. H. Tutton found that commercial phosphoric oxide slowly acquires a yellow colour on exposure to light, and it becomes red in direct sunlight. Phosphorus pentoxide is extremely hygroscopic, and it dissolves in water with a hissing sound as if it were a red-hot powder; it absorbs moisture from the air very quickly, hence its use for drying gases—*vide* **hydrogen, 1.** 7, 2. P. Neogi and B. B. Adhicary observed that phosphine is produced when hydrogen is passed over a mixture of phosphorus pentoxide and reduced nickel at a dull red-heat. The affinity of phosphoric oxide for **water** is so great that it can withdraw the elements of water from many organic and inorganic substances—*e.g.* it converts nitric acid to nitrogen pentoxide, N_2O_5; it converts alcohol into ethylene, C_2H_4; sulphuric acid to sulphur trioxide, SO_3; etc. P. Hautefeuille and A. Perrey found that the crystallized oxide dissolves very rapidly in water, forming a clear soln., the pulverulent oxide forms transparent gelatinous clots which dissolve more slowly; the vitreous oxide dissolves but slowly in water. According to H. Biltz, no trace of red phosphorus or of a phosphorus suboxide is produced when phosphoric oxide deliquesces, or when it is dissolved in much water, yet there is a distinct smell of phosphorus when water is gradually added to the ordinary oxide, but not to the highly purified oxide. H. Biltz believes that phosphorus tetritoxide is formed by passing water-vapour over phosphorus pentoxide; he said that he obtained 6 mgrms. of the tetritoxide from 10 grms. of the pentoxide, and that the hot water decomposes a part of the tetritoxide to form phosphine, PH_3. The soln. of phosphoric oxide in water is phosphoric acid (*q.v.*). E. B. R. Prideaux found that with an excess of water at room temp., about 75 per cent. of the dissolved oxide is in the form of metaphosphoric acid, HPO_3, and the remainder as orthophosphoric acid, H_3PO_4. No pyrophosphoric acid, $H_4P_2O_7$, was observed. The soln. reddens blue litmus—*vide infra,* phosphoric acid. Dry phosphorus pentoxide has no action on dry litmus paper.

H. Moissan[11] found that cold phosphorus pentoxide does not react with **fluorine,** but at a dark red-heat, a flame is produced and phosphorus pentafluoride and oxyfluoride are formed. According to G. Gore, phosphorus pentoxide unites vigorously with dry **hydrogen fluoride,** forming, below 19·5°, phosphoryl fluoride, POF_3, so that the oxide cannot be used as a desiccating agent for hydrogen fluoride. G. H. Bailey and G. J. Fowler also showed that dry **hydrogen chloride** is slowly absorbed by phosphorus pentoxide, and the absorbed gas is not all given off when the product is placed in vacuo. When phosphorus pentoxide is saturated with dry hydrogen chloride, it becomes liquid, and the liquid, on distillation, gives off phosphoryl chloride, $POCl_3$, and leaves a residue of metaphosphoric acid, HPO_3. **Hydrogen bromide** behaves in a similar manner; but **hydrogen iodide** is not absorbed. Phosphorus pentoxide reacts with **sulphuric acid,** furnishing sulphur trioxide; and R. Weber found that **sulphur trioxide** unites with the phosphoric oxide, forming $P_2O_5.3SO_3$—*vide infra,* phosphoryl sulphate. H. Prinz observed no reaction with **sulphur monochloride,** S_2Cl_2, at 230°.

There is no reaction between phosphoric oxide and **nitrogen.** Phosphorus pentoxide reacts with **nitric acid,** forming nitrogen pentoxide (*q.v.*). The reaction was studied by R. Weber,[12] and J. Giersbach and A. Kessler showed that the reaction is violent only when the nitric acid contains a considerable proportion of water. H. Biltz noticed that commercial phosphorus pentoxide reacts vigorously with **ammonia,** and, with stronger heating, forms reddish-brown flecks of red phosphorus or phosphorus tetritoxide, and phosphamic acid, $P_2O_3(OH)_2$. H. Biltz found that phosphorus pentoxide which has been distilled with oxygen over spongy platinum does not show these reactions. H. Schiff found that with ammonia, amidophosphoric acid (*q.v.*) is formed; and at 0°, A. Mente found imidodiphosphoric acid (*q.v.*) is produced. G. Gustavson heated a mixture of phosphorus pentoxide and **phosphoryl chloride** in a sealed-tube at 200°, and obtained a product which he regarded as phosphorus dioxychloride, PO_2Cl, by the reaction: $P_2O_5+POCl_3=3PO_2Cl$, but G. N. Huntly distilled off the excess of phosphoryl chloride, and obtained a residue which had the empirical composition, $P_2O_5.POCl_3$, and from which carbon disulphide extracted a substance with the empirical composition, $P_2O_3Cl_4$, and left a residue, $P_7O_{13}Cl_5$. E. Berger also found that **phosphorus pentabromide** gives the phosphoryl bromide: $3PBr_5+P_2O_5=5POBr_3$. F. E. Brown and J. E. Snyder said that **vanadium oxytrichloride** is without action on phosphorus pentoxide. G. Gustavson found **boron trichloride** under similar conditions gave $P_2O_5+2BCl_3=POCl_3.BCl_3+PBO_4$, the latter may be a compound, $P_2O_5.B_2O_3$. The latter product is also formed when phosphorus pentoxide and **boric acid** are heated together. P. Hautefeuille and J. Margottet prepared the product $P_2O_5.SiO_2.4H_2O$ by heating **silica** with phosphoric acid; they have also described corresponding compounds with **titanium, zirconium, and stannic oxides.** O. Nielson studied the reaction with silica (*q.v.*).

When heated with **carbon,** H. Davy noted that phosphoric oxide is decomposed with the evolution of phosphorus and carbon monoxide. G. Gustavson heated phosphorus pentoxide with **carbon tetrachloride** in a sealed tube at 200°–300° for 48 hrs., and obtained: $P_2O_5+2CCl_4=COCl_2+CO_2+2POCl_3$; and with a smaller proportion of the carbon tetrachloride: $2P_2O_5+3CCl_4=4POCl_3+3CO_2$. The dehydrating action of phosphorus pentoxide on numerous organic compounds has been investigated; thus, H. Gal and A. Étard [13] examined its action on **acetic and benzoic acids**; L. Vanino and L. Seemann, on **formaldehyde**; F. S. Kipping, on **fatty acids**; B. Maikopar, on **phenol**; H. Biltz, on **aniline**; R. Lespieau, on **dibromopropane.** M. A. Rakusin and A. A. Arsenéeff found that phosphorus pentoxide readily dissolves to the extent of 60 per cent. in **ethyl and methyl alcohols** with the development of heat. Considerably greater quantities of the oxide dissolve in the resulting liquids, on continued stirring and heating, up to 295 g. in the case of methyl alcohol, giving a liquid of sp. gr. 1·5437 at 15 and up to 258 g. in the case of ethyl alcohol, giving a liquid of sp. gr. 1·5894 at 15°. These liquids react acid and do not boil on adding water, or give a precipitate with silver nitrate soln. H. Meerwein observed no formation of complex alkali salts by phosphorus alkoxide. W. Balareff studied the dynamics of the catalytic decomposition of ethyl alcohol by phosphorus pentoxide. Phosphorus pentoxide causes **phenol, menthol,** and similar substances to dissolve in **chloroform** without apparently entering into any reaction with them. If the soln. are left for several days and the chloroform is then removed by a current of dry air, the phosphoric oxide and the phenol are recovered unchanged.

L. Kahlenberg and W. J. Trautmann [14] observed no reaction when the pentoxide is heated with **silicon.** H. Davy found that when phosphorus pentoxide is warmed with **potassium** or **sodium,** the mixture becomes incandescent, forming the metal phosphide and phosphate; similarly with **zinc, iron,** etc., at a red-heat. H. Moissan said that it is reduced by **calcium** with explosion below redness; and by **columbium** at a red-heat. E. Solvay and M. Lucion observed a vigorous reaction between the pentoxide and **sodium oxide,** or **calcium oxide.** According to W. Odling, salts of the volatile acid anhydrides are decomposed when heated with phosphoric oxide forming phosphates and the volatile anhydride. T. E. Thorpe and F. J. Hambly found that when phosphorus pentoxide is heated with **cryolite,** phosphorus oxyfluoride, POF_3, is formed; H. Kolbe and E. Lautemann found with **sodium chloride,** phosphorus oxyfluoride, $POCl_3$, is formed; with **iodides,** C. F. Schönbein reported a turbulent reaction and the evolution of iodine; and with **selenites,** J. J. Berzelius found that selenium dioxide is given off.

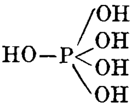
§ 24. Orthophosphoric Acid

> No substance offers the chemist greater difficulties than phosphoric acid; the more the behaviour of the acid is studied, the more the difficulties increase. Every new investigation presents the chemist with new anomalies; fresh and puzzling phenomena make their appearance, whilst the older and already known difficulties are by no means cleared up.—H. Rose.

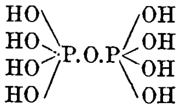
R. Boyle[1] was the first to prepare phosphoric acid. This he did by showing that the action of water on the products of combustion of phosphorus furnishes a liquid with acid properties. G. Homberg obtained similar results. F. Hoffmann supposed phosphoric acid to be a compound of vitriolic and hydrochloric acids; and G. E. Stahl, and J. Hellot argued that phosphoric acid is a compound of phlogiston with hydrochloric acid, apparently because urine contains much sodium chloride, and phosphoric acid can be extracted from urine. H. Boerhaave regarded phosphoric acid as a substance similar to sulphuric acid; and a year later, A. G. Hanckewitz, in a paper before the Royal Society, could not decide whether phosphorus is or is not a compound of sulphur. Like R. Boyle, A. S. Marggraf prepared phosphoric acid by dissolving *fleurs de phosphore* in water, and extracted it from the salts contained in urine. A. S. Marggraf also described the physical and chemical properties of phosphoric acid. As indicated in connection with the history of phosphorus, C. W. Scheele or J. G. Gann, or both, extracted the acid from bones; and in the same year, A. L. Lavoisier showed that phosphoric anhydride is a compound of phosphorus and oxygen, and established the elementary nature of phosphorus. A. L. Lavoisier prepared phosphoric acid by the action of nitric acid on phosphorus.

It was once thought that phosphoric acid existed in three isomeric forms: (i) The ordinary acid prepared by R. Boyle, and S. A. Marggraf. The sodium salt of this acid gives a yellow precipitate with silver nitrate, and the liquid possessed an acid reaction. (ii) A salt of an acid was prepared by T. Clark in 1827 by heating the ordinary phosphate. The sodium salt of this acid gives a white precipitate with silver nitrate, and the liquid remains neutral. (iii) The acid obtained by J. J. Berzelius, by a thorough calcination of phosphoric acid. This acid also gives a white precipitate with silver nitrate, and, unlike the other two forms, coagulated a clear aq. soln. of albumen. It was known that the sodium salts of ordinary and of T. Clark's phosphoric acid crystallized from aq. soln. with different amounts of water, but no importance was attached to this fact because it was regarded simply as water of crystallization. F. Stromeyer, and others supposed the two acids to be isomeric modifications. J. L. Gay Lussac made a special study of the salts of T. Clark's acid. In 1833, T. Graham showed that the water of the acids should not be disregarded as an accidental feature because the water plays an essential part in the formation of the acid where it assumes the function of a base. Thomas Graham proved that all three acids—which he called respectively ordinary, pyro-, and metaphosphoric acids—were different modifications of phosphoric acid; and that they differed from one another by "the quantity of water combined with the acid." In orthophosphoric acid, the water and anhydride are united in the proportion $3H_2O : P_2O_5$; in pyrophosphoric acid, $2H_2O : P_2O_5$; and in metaphosphoric acid, $H_2O.P_2O_5$. T. Graham also found that when the acids were saturated with a base, three series of phosphates were obtained, one series contained one equivalent of the base per equivalent of the anhydride—*primary phosphates;* a second series contained two equivalents of the base—*secondary phosphates;* and a third series contained three equivalents of the base—*tertiary phosphates.*

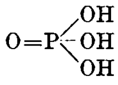
The relation of the three phosphoric acids to phosphoric oxide, P_2O_5, will be evident from the following scheme, where phosphorus is assumed to be quinquevalent:



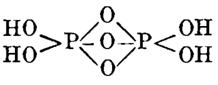
H_5PO_5, or
$P_2O_5.5H_2O$



$H_8P_2O_9$, or
$P_2O_5.4H_2O$



H_3PO_4, or
$P_2O_5.3H_2O$



$H_4P_2O_7$, or
$P_2O_5.2H_2O$

HPO_3, or
$P_2O_5.H_2O$

The first two are unknown, the third is ordinary orthophosphoric acid, the fourth pyrophosphoric acid, and the last metaphosphoric acid. I. Fröschl[2] accounted for the different behaviour of the five hydroxyl groups in phosphoric acid by assuming that in the strictly orthophosphoric acid, $P(OH)_5$, three have an acidic character, one is amphoteric, and one is basic. Hence, complex salts should be possible, and he prepared **sodium carbonatophosphate,** $Na_2H_3(CO_3)(PO_4)$; **potassium disulphatophosphate,** $2K_2SO_4.H_3PO_4$; **potassium sulphatophosphate,** $K_2SO_4.H_3PO_4$; **ammonium sulphatophosphate,** $(NH_4)_2SO_4.(NH_4)H_2PO_4$. The minerals apatite, wagnerite, and dahllite are supposed to belong to the same class of salts, and also the fluophosphates described by R. F. Weinland and J. Alfa. P. Lemoult reported a number of derivatives of pentabasic phosphoric acid, $P(OH)_5$, of the type $P(OH)(NH.R)_4$. It will be observed that by keeping consistently to the notation employed for periodic acid, and several other acids, the unknown $P(OH)_5$ should be *orthophosphoric acid,* but this term has got into use for the $PO(OH)_3$-acid, which ought to be called *paraphosphoric acid,* $PO_2(OH)$; and **metaphosphoric acid** would retain its present designation. Similarly, $(HO)_4P.O.P(OH)_4$ would be called *orthodiphosphoric acid,* or *orthopyrophosphoric acid.* Hemihydrated phosphoric acid may be regarded as *orthodiphosphoric acid;* and the mineral libethenite as the calcium salt—*vide infra.* The next dehydration product, $(HO)_3P{=}O_2{=}P(OH)_3$, would be *paradiphosphoric acid* or *diparaphosphoric acid,* $(H_3PO_4)_2$; while $(HO)_2P{\equiv}O_3{\equiv}P(OH)_2$, at present called *pyrophosphoric acid* or *diphosphoric acid,* becomes *mesodiphosphoric acid*; $(HO)P{\equiv}O_4{\equiv}P(OH)$ is the ordinary *metadiphosphoric acid—vide infra.*

Orthophosphoric acid or salt of the acid was formed by A. J. Balard,[3] E. Soubeiran, T. J. Pelouze, M. Bengeiser, A. R. Leeds, etc., by passing phosphorus vapour over red-hot alkali carbonate, or by the action of an oxidizing agent; sulphur trioxide or sulphuric acid; nitrous or nitric oxide; nitrogen peroxide; or nitric acid. It is also formed by the action of phosphorus on an iodate, periodate, bromate, chlorate, perchlorate, nitrate, or metal oxide whereby a mixture of metal phosphate and phosphide is formed. Some of these reactions are dangerously explosive. Phosphoric acid can be made by boiling an aq. soln. of the products of combustion of phosphorus with nitric acid so as to oxidize the lower oxides, and to transform the meta- into orthophosphoric acid. Meta- and pyrophosphoric acids can be hydrated to the ortho-acid by the action of heat in the presence of strong acids. The acids of the lower oxides—H_3PO_2, H_2PO_3, and $H_4P_2O_6$—can be oxidized to orthophosphoric acid. Thus, A. Michaelis and M. Pitsch oxidized the tetritoxide by iodine, sodium hypochlorite, or sulphuric acid; H. Rose oxidized hypophosphorous acid by heating it in air, and by the action of hypochlorous or nitric acid; P. L. Dulong used iodine or chlorine, and also soln. of mercury, silver, or gold salts. C. A. Wurtz oxidized phosphorous acid by prolonged exposure to air or by treatment with conc. sulphuric acid; H. Davy used chlorine, hypochlorous acid, iodic acid, nitric acid, and salts of mercury, gold, silver, etc. A. Cavazzi oxidized phosphine by treatment with sulphur acid at 60° or 70°; H. Rose used conc. sulphuric acid at ordinary temp.; and P. Thénard, chlorine-water. C. F. Bucholz boiled B. Pelletier's acid with nitric acid. A. Sommer recommended oxidation with bromine when hydrobromic acid is obtained as a by-product. M. Pettenkofer also recommended making phosphoric acid by boiling with nitric acid the by-product obtained in the preparation of hydriodic acid from iodine, phosphorus, and water. F. G. Liljenroth made the acid by the action of hot water or steam on phosphides with or without a catalyst; and E. Urbain recovered the phosphorus evolved in the preparation of activated carbon, in the form of phosphoric acid by a modification of this process.

A great many chemists—M. Martres, etc.—have described the preparation of phosphoric acid by the action of boiling nitric acid on phosphorus. The method was employed by A. L. Lavoisier in 1780, and strongly recommended by T. Bergman, who said: "Nothing but a prudent management of the fire is required to procure the acid with the greatest ease in a state of as great purity as by the tedious and wasteful method of combustion in air." Phosphorus is scarcely attacked even by 6 months' contact with cold dilute nitric acid of sp. gr. 1·012, but with more concentrated acid, the action is more marked. Some ammonia is formed during the reaction, and the amount reaches a maximum with nitric acid of sp. gr. 1·18.

Orthophosphoric acid is conveniently prepared by boiling one part of red phosphorus with 16 parts of nitric acid—sp. gr. between 1·20 and 1·25—in a flask fitted with a reflux condenser and a ground glass-joint at the neck. Any nitric acid which is volatilized will thus be returned to the flask. Yellow phosphorus is not so quickly attacked by nitric acid as red phosphorus, possibly because the former melts and forms masses which do not present so nearly as large a surface to the action of the acid as do the particles of red phosphorus. The latter is more expensive. When the phosphorus is all oxidized, the soln. is evaporated to dryness, and the residue is finally heated in a platinum dish to a temp. not exceeding 180° to make sure that all the nitric acid is driven off. The boiling liquid usually shows the presence of phosphorous acid, which is subsequently oxidized to phosphoric acid. Whether the primary action results in the formation of both acids or of phosphorous acid alone is not clear. If the acid employed for the oxidation be more conc. than that just indicated an explosion may ensue; and if a weaker acid be used the action is very slow.

M. Pettenkofer, W. J. Horn, and G. A. Ziegeler showed that the presence of a trace of iodine will accelerate the reaction, which then runs more smoothly. G. A. Ziegeler recommends 0·3 to 0·6 grm. of iodine per 100 grms. of phosphorus. P. Wagner, and G. F. H. Markoe noted that bromine acts in a similar way. The nitric acid should be free from sulphuric acid.

If the phosphorus contains arsenic, the phosphoric acid will be contaminated with arsenic acid. W. T. Wenzell, E. W. Runyon, L. A. Buchner, G. Watson, J. von Liebig, C. F. Bärwald, etc., have described processes for eliminating the arsenic. In these, the aq. soln. of the acid is sat. with hydrogen sulphide, and allowed to stand some days in a closed flask; renewal of the hydrogen sulphide is necessary from time to time. The filtered liquid is freed from hydrogen sulphide by evaporation. W. Gregory purified phosphoric acid by heating it between 320° and 350° so as to transform it into metaphosphoric acid, and the impurities into insoluble metaphosphates. The metaphosphoric acid is leached out by water, and transformed into orthophosphoric acid as indicated above. The process of purification—J. B. Trommsdorff, G. Watson, H. W. F. Wackenroder, etc.—by precipitating the impurities with alcohol is too expensive. A. J. Balard, and P. L. Dulong precipitated the calcium phosphate (and magnesium phosphate) with ammonium carbonate. According to R. Maddrell, the acid purified by W. Gregory's process still retains magnesium and sodium phosphates. In J. N. Carothers and A. B. Gerber's process, conc. phosphoric acid is partially freed from arsenic, lead, lime, and fluorine by chemical methods, and is then subjected to a current of air at a temperature of 50° to remove volatile impurities. The suspended solids are then separated and the acid cooled, when crystalline phosphoric acid separates. B. Laporte treated sodium phosphate with barium sulphide, etc.: $3BaS + 2NaOH + 2Na_2HPO_4 = Ba_3(PO_4)_2 + 3Na_2S + 2H_2O$; and the washed barium phosphate is treated with sulphuric acid, etc.

Phosphoric acid is not usually prepared in the laboratory because an acid of a high degree of purity can be readily obtained in commerce. Only in special cases is the preparation conducted in the laboratory. The hydrolysis of the phosphoric or phosphoryl halides—PF_5, POF_3, PCl_5, $POCl_3$, PBr_5, and $POBr_3$—furnishes fairly pure phosphoric acid, $PCl_5 + 4H_2O = H_3PO_4 + 5HCl$, when the volatile acid has been removed by evaporation in a platinum dish. A. Geuther and A. Michaelis found that phosphoric acid is likewise produced by the action of pyrophosphoryl chloride on water. H. E. W. Phillips prepared the acid in the following manner:

> Phosphorus trichloride twice redistilled was mixed very slowly with specially purified water, the flat porcelain dish in which the addition was made being floated on cold water during the operation. It was found that, if the addition was made too rapidly, a discoloration was produced, which at the end of the preparation was seen to be due to a fine powder suspended in the liquid. The phosphorous acid was then heated until it gave no precipitate with silver nitrate. It was then oxidized by cautious addition of dil. nitric acid, when an active effervescence ensued. Nitric acid was eventually added in slight excess, and the evaporation continued until all the nitric acid was expelled. The phosphoric acid thus prepared was transparent and colourless. The 100 per cent. acid did not affect litmus paper, and had no action on sodium carbonate.

A. Joly[4] recommended treating purified ammonium phosphate with boiling conc. hydrochloric acid. The liquid was separated from the precipitated ammonium chloride, and heated with nitric acid to drive off the ammonia and hydrochloric acid. The nitric acid is expelled by evaporating the soln. as indicated above. A. Ditte, and G. Watson used sodium phosphate and conc. hydrochloric acid; M. Nicolas, calcium phosphate or natural phosphates and hydrofluoric acid; A. Gutensohn heated aluminium phosphate with tin shavings in an iron vessel; H. N. Warren electrolyzed a soln. of copper phosphate in dil. phosphoric acid; J. J. Berzelius prepared lead phosphate by adding a soln. of lead acetate to a nitric acid soln. of bone-ash, and decomposed the lead phosphate by treatment with dil. sulphuric acid, and removed the last traces of lead by hydrogen sulphide; and W. Odling treated a soln. of sodium phosphate in ice-cold water with lead acetate, and decomposed the washed precipitate suspended in water with hydrogen sulphide. The soln., freed from the precipitated lead sulphide, was evaporated to remove the hydrogen sulphide. J. Persoz digested the soln. of bone-ash with ferric or aluminium oxide, decomposed the precipitated phosphate with sulphuric acid, and afterwards extracted with phosphoric acid with alcohol. L. Thompson precipitated the lime by treating the calcium phosphate with oxalic acid. W. H. Ross and co-workers purified phosphoric acid by a process of fractional crystallization.

Industrially, phosphoric acid has been prepared from bone-ash, from natural phosphates, or from Thomas-slag. Many processes have been suggested,[5] and patent specifications filed,—*e.g.* by A. Adair and W. Thomlinson, H. and E. Albert, A. J. Balard, L. Blum, M. Brandon, A. Colson, G. Deumelandt, A. Drevermann, P. Dietrich, E. Dreyfus, P. L. Dulong, J. M. J. Funke, W. Gregory, R. Hasenclever, M. Hatmaker, J. Meckstroth, A. House, L. Carpenter, R. Suchy, A. Aita, H. G. C. Fairweather, W. G. Waldo, E. W. Guernsey and J. Y. Yee, J. N. Carothers, K. D. Jacob, L. Imperatori, G. Leuchs, J. von Liebig, T. Lomax, R. Maddrell, H. Merz, T. Meyer, J. Neustadl, N. B. Powter, G. Rocoeur, F. S. Washburn, A. Rose, C. Runzler, W. H. Ross and co-workers, C. Scheibler, R. Schliwa,

S. G. Thomas, S. G. Thomas and T. Twymann, J. B. Trommsdorff. In many of these the phosphate is treated with the calculated quantity of dil. sulphuric acid for precipitating the lime, and after the mixture has stood some time, it is pumped through a filter-press so as to separate the calcium sulphate precipitate from the phosphoric acid which has a sp. gr. approximating 1·07 or 1·09. The liquor is then evaporated in lead pans until its sp. gr. is nearly 1·53. If necessary, the acid can be treated with more sulphuric acid to precipitate more calcium sulphate, and the clear liquor evaporated to dryness, and ignited to drive off the excess of acid. The product is nearly free from lime and sulphuric acid, but retains magnesium phosphate. The cakes from the filter-press are used for agricultural purposes. W. H. Waggaman and co-workers, T. Swann, W. Kyber, and W. H. Ross and co-workers described the preparation of phosphoric acid from phosphatic rocks by heating at a high temp. a mixture of the natural phosphate with silica and coke, and collecting the volatilized phosphoric acid in a suitable chamber. A calcium silicate slag remains. F. J. Maywald heated the mixed phosphates by a low potential arc, and collected the volatilized phosphoric acid. The volatilized acid prepared by the volatilization process is at least of an equal degree of purity with that prepared by the sulphuric acid process.

Table III by W. H. Ross[6] and co-workers shows the amount of impurity in some commercial phosphoric acids prepared by the sulphuric acid process *S* and by the volatilization process *V* from phosphate rock *R* or bones *B*. The commercial acid may be crude *C* or refined *P*. Arsenic and lead are expressed in parts per million. The lead is largely derived from the lead containers. The presence of *phosphorous acid* as an impurity in phosphoric acid is revealed by its giving a black instead of a yellow precipitate with mercurous nitrate; a precipitate of sulphur when heated with sulphurous acid; and evolving phosphine when heated with dil. sulphuric acid. The presence of metaphosphoric acid is indicated by the white precipitate obtained by its coagulating white-of-egg.

TABLE III.—THE COMPOSITION OF SOME COMMERCIAL PHOSPHORIC ACIDS.

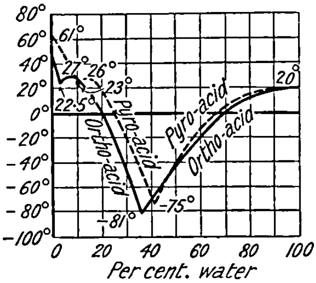

FIG. 40.—Freezing-point Curves of Water with Orthophosphoric Acid and with Pyrophosphoric Acid.

The hydrates of phosphoric acid.—J. F. H. Süersen[7] found the crystals of phosphoric acid to be easily soluble in water, and H. Giran obtained the results shown by the continuous curve, Fig. 40, for the f.p. of mixtures of orthophosphoric acid and water. There are two minima, 22·5° and —81°; the former corresponds with $H_3PO_4+0{\cdot}135H_2O$, and the other with $H_3PO_4+3{\cdot}205H_2O$, the maximum occurring with the hemihydrate. W. H. Ross and R. M. Jones gave —85° for the one eutectic temp., and 23·50° for the other. A. Smith and A. W. C. Menzies have measured the solubility of the ortho-acid in water at different temp. The results constitute a more detailed study of the f.p. curve for the more conc. soln. of orthophosphoric acid. The following numbers are selected from their data:

	−16·3°	0·5°	27°	29·35°	25·41°	24·11°	25·85°	26·23°	42·30°
Per cent. H_3PO_4 .	76·7	78·7	87·7	91·6	94·1	94·78	95·54	95·90	100
Solid phases . .	$2H_3PO_4.H_2O$					$10H_3PO_4.H_2O$		H_3PO_4	

The results are graphed in Fig. 41. *AB* is the solubility curve of A. Joly's hydrate. $2H_3PO_4.H_2O$; *B* is the melting point of this hydrate (29·35°); *BC*, the effect of phosphoric acid on the m.p. of the hemihydrate; *CD*, the solubility curve of $10H_3PO_4.H_2O$; and *C* is the eutectic point (23·5°) of the two hydrates; *D* is the transition point (26·2°); *DE* is the solubility curve of orthophosphoric acid; and *E* is the melting point (42·30°) of orthophosphoric acid. W. H. Ross and R. M. Jones observed no break in the curve at *D*, and were unable to confirm the existence of the hydrate, $10H_3PO_4.H_2O$. J. Kendall and co-workers studied the hydrate formation with this and related acids.

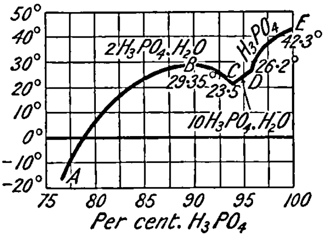

FIG. 41.—Solubility Curve of Orthophosphoric Acid.

According to A. Joly, if a conc. soln. of the approximate composition $H_3PO_4 + 0·3H_2O$ be sown with a crystal of phosphoric acid, the mother-liquid remaining after the crystallization has the composition $2H_2PO_4.H_2O$, and this solidifies to a mass of prismatic plates of **hemihydrated orthophosphoric acid,** $2H_3PO_4.H_2O$. The undercooled soln. of this hydrate crystallizes when sown with crystals of the isomorphous hemihydrated arsenic acid. A. Smith and A. W. C. Menzies have found that A. Joly's hydrate is stable between —16·3° and 25·41°. It has been suggested that the hemihydrate $2H_3PO_4.H_2O$ is really an octobasic phosphoric acid, or orthodiphosphoric acid, $H_8P_2O_9$, represented by the salts, tetracalcium phosphate, $Ca_4P_2O_9$; *libethenite,* $Cu_4P_2O_9.H_2O$, etc. Since orthophosphoric acid is probably $H_6P_2O_4$, the theoretical hydroxyl derivatives with a $\equiv P-O-P\equiv$ nucleus are:

Acid . .	$(HO)_8P_2O$	$(HO)_6P_2O_2$	$(HO)_4P_2O_3$	$(HO)_2P_2O_4$
Calcium salt	$Ca_4P_2O_9$	$Ca_3P_2O_8$	$Ca_2P_2O_7$	CaP_2O_6
	Orthopyrophosphoric acid.	Paradiphosphoric acid.	Metapyrophosphoric acid.	Metaphosphoric acid.

A. Smith and A. W. C. Menzies obtained **decitahydrated orthophosphoric acid,** $10H_3PO_4.H_2O$, stable between —24·11° and 25·85°, Fig. 41. This hydrate forms large transparent prisms which pass into anhydrous orthophosphoric acid, H_3PO_4, at 26·2°. W. H. Ross and R. M. Jones were unable to confirm these observations. P. L. Huskisson found crystals which had separated from a sample of sp. gr. 1·750 (88·8 per cent.) induced crystallization in acids of specific gravity from 1·66 (82 per cent.) to 1·75 at ordinary temp., but not so in acids of higher or lower specific gravity. The work of A. Smith and A. W. C. Menzies shows that the crystals were those of the hemihydrate, $2H_3PO_4.H_2O$, and if P. L. Huskisson had worked below 13° he would have obtained crystals from the less conc. soln. The crystals P. L. Huskisson obtained by allowing a soln. of sp. gr. 1·75 to stand in vacuo were those of H_3PO_4; and in such soln., the crystals of the hemihydrate induced no crystallization. The formation of the hydrates was discussed by J. Kendall and co-workers. Attempts by A. Sänger to prepare the *monohydrated orthophosphoric acid,* $H_3PO_4.H_2O$, *i.e.* $P(OH)_5$, were not successful, although P. Lemoult did prepare organic derivatives of pentabasic phosphoric acid, $RO.P(NH.R)_4$. H. Crompton found that the second differential of the electrical conductivity gave breaks corresponding with the hydrates $H_3PO_4.2H_2O$, and $H_3PO_4.7H_2O$, which are the same as those found by D. I. Mendeléeff from the first differential coefficient of the sp. gr. curves—*vide* sulphuric acid.

The physical properties of phosphoric acid.—J. F. H. Süersen,[8] P. A. Steinacher, and F. Stromeyer noted that spontaneous crystallization occurs if the viscid liquid be left at rest for some days. The transparent crystals are either four-sided prisms or six-sided prisms with quadrilateral summits. A. Joly said that the **crystals** belong to the rhombic system. According to G. Tammann, when the soln. of phosphoric acid has been evaporated to the point where the bubbling and spurting suddenly cease, the syrupy liquid has a composition corresponding with H_3PO_4; and, according to G. Krämer, this liquid furnishes transparent prismatic crystals on cooling. The syrupy liquid does not crystallize readily owing to surfusion. W. H. Ross and R. M. Jones saw that the rates of crystallization of the hemihydrated and anhydrous phosphoric acid are respectively 2·6 cms. and 33·3 cms. per minute at 22°. If the conc. be carried further than this, H. P. Cooper said that the liquid gelatinizes and some pyro- and meta-phosphoric acids are formed; but P. L. Huskisson stated that if the evaporation be conducted in vacuo beyond a sp. gr. 1·860, transparent plates are formed which become opaque with the development of heat on exposure to air. H. E. W. Phillips did not find the 100 per cent. acid to crystallize, except occasionally when cooled to 0°. J. Thomsen found the conc. soln. of the acid crystallizes readily if sown with some crystals of the solid acid. H. P. Cooper said that a crystal of Glauber's salt in a soln. of sp. gr. 1·850, crystallizes rapidly, but this statement is probably a *mal*-interpretation of the observed result, and is not a true case of crystallization by seeding. Crystallization occurs rapidly with the development of heat by the inoculation of a soln. of sp. gr. 1·750 with a crystal of orthophosphoric acid; with a soln. of sp. gr. 1·660, crystallization proceeds more slowly, and furnishes prismatic needles. The crystals are deliquescent. J. Dalton [9] measured the **specific gravity** of a few solutions of phosphoric acid of known composition. According to H. Schiff, the sp. gr. of the syrupy liquid of the composition H_3PO_4 is 1·88, and he represented the sp. gr., D, of a soln. with p per cent. of phosphoric acid, H_3PO_4, by the formula $D=1+0{\cdot}005378p+0{\cdot}00002886p^2+0{\cdot}00000006p^3$. Tables have been prepared by H. Watts, H. Schiff and A. Ott, etc. The results by H. Hager are indicated in Table IV. If the percentage of P_2O_5 be multiplied by 1·38, it furnishes the corresponding amount of H_3PO_4. Observations were also made by N. P. Knowlton and A. C. Mounce, D. I. Mendeléeff, W. H. Ross and R. M. Jones, W. Thörner, and F. K. Cameron and W. O. Robinson. E. Cornec measured the sp. gr. of soln. of phosphoric acid while being progressively neutralized by potassium hydroxide, and found a marked minimum corresponding with the dihydrophosphate, and a maximum corresponding with the normal

TABLE IV.—THE SPECIFIC GRAVITY OF AQUEOUS SOLUTIONS OF PHOSPHORIC ACID OF DIFFERENT CONCENTRATIONS.

Per cent. P_2O_5	Specific gravities at 17·5°.

phosphate. The **viscosity** of soln. of phosphoric acid have been measured by J. L. M. Poisseville,[10] K. T. Slotte, etc. With water unity, R. Reyher found for N-, $\frac{1}{2}N$-, $\frac{1}{4}N$-, and $\frac{1}{8}N$-soln., at 25°, respectively 1·2871, 1·1331, 1·0656, and 1·0312; and B. E. Moore, at 18°, for soln. with 0·25, 0·5, 1·0, and 2·0 mols per litre, the respective values 1·064, 1·143, 1·311, and 1·739. A. Smith and A. W. C. Menzies found no maximum in the solubility curve of mixtures of 90·6 to 98·1 per cent. of orthophosphoric acid with water. L. J. Simon measured the viscosity of phosphoric acid while being neutralized with sodium hydroxide. T. Graham found that the **rate of diffusion** of phosphoric acid is such that in eight days 9·1 grms. of the acid diffused from a soln. of 4 grains of H_3PO_4 in 100 grms. of water at 15·6°. For phosphoric acid, at 20°, L. W. Oholm gave for $3N$-, $2N$-, N-, and $0{\cdot}25N$-soln., $k=0{\cdot}644$, 0·656, 0·692, and 0·772 respectively. The **coefficients of cubical expansion** of soln. of phosphoric acid were determined by C. Forch,[11] W. Thörner, and H. Schiff. C. Forch gave:

Per cent.	0°–5°	5°–10°	10°–15°	15°–20°	20°–25°	25°–30°	30°–35°	35°–40°
4·8	48	109	164	220	266	309	352	387
17·8	188	228	267	304	337	371	399	430

The true **melting point** of orthophosphoric acid is difficult to determine on account of the depression which is produced by traces of water absorbed by the hygroscopic crystals. J. Thomsen[12] found 38·6°; W. Borodowsky, 36·6°; M. Berthelot, 41·75°; A. Smith and A. W. C. Menzies, 42·30°; and W. H. Ross and R. M. Jones, 42·35°. G. Tammann represented the effect of press. p kgrms. per sq. cm., on the m.p., θ°, of orthophosphoric acid by $\theta=38{\cdot}0+0{\cdot}00800p$, or

θ	38·3	40·93°	44·98°	49·94°	54·93°	59·98°
p	1	410	960	1500	2032	2695

H. Giran measured the f.p. curve of mixtures of orthophosphoric acid and water. His curve shows two minima, one at 22·5° and one at —81°, with one maximum at 29°, and he concluded that 29° is the m.p. of the hemihydrate. The minimum —81° is probably the cryohydric point for the mixture $H_3PO_4+0{\cdot}135H_2O$. H. Giran's m.p. of $2H_3PO_4.H_2O$, 29°, is two degrees higher than A. Joly's own value, 27°. A. Smith and A. W. C. Menzies give 29·35°; and W. H. Ross and R. M. Jones, 29·32°. Probably owing to undercooling effects, H. Giran missed the decitahydrate. For the m.p. of mixtures of phosphorous and phosphoric acids, *vide* Fig. 37. J. Kendall and co-workers, and H. C. Jones measured the mol. **lowering of the freezing point** in aq. soln., and calculated values for the degree of ionization. G. Rümelin[13] found for soln. with 15·41, 21·57, 28·21, and 32·75 per cent. H_3PO_4, the **specific heats** 0·834, 0·813, 0·776, and 0·697 respectively.

The **vapour pressures** of aq. soln. of orthophosphoric acid were measured by L. von Babo[14] in 1847; at the b.p. 122°, the vap. press. is 760 mm.; at 35°, 20 mm.; at 65°, 92 mm.; and at 78°, 164 mm. C. Dieterici found at 0° soln. with 0·945, 22·32, 124·9, and 390·2 grms. in 100 grms. of water had a vap. press. of 4·612, 4·377, 2·710, and 0·636 mm. respectively. G. Tammann measured the lowering of the vap. press. of water at 100°, and found with 20·75, 149·16, and 330·52 grms. of phosphoric acid in 100 grms. of water lowered the vap. press. respectively 30·1, 290·9, and 507·3 mm. A. Smith and A. W. C. Menzies found the vap. press. of the hydrate systems attained a state of equilibrium very slowly; a sat. soln. of the hydrate $2H_3PO_4.H_2O$ at 24·99° had a vap. press. of 0·85 mm. I. Fröschl measured the mol. wts. determined by the **elevation of the boiling point** for soln. of different conc., and the resulting curve exhibited discontinuities with 7 and 13 per cent. of H_3PO_4. For soln. with 1 to 6·5 per cent. H_3PO_4, the mol. wt. was 137·2; with soln. 7 to 12 per cent. H_3PO_4, 125·9; and with soln. 14 to 27 per cent. H_3PO_4, 115·7—the theoretical value for H_3PO_4 is 98.

J. Thomsen[15] gave —2·52 Cals. for the **heat of fusion** of orthophosphoric acid, H_3PO_4; and A. Joly, —7·28 Cals., for the heat of fusion of the hemihydrate, $2H_3PO_4.H_2O$. J. Thomsen gave for the **heat of formation** $(H_3,P,O_4)=302{\cdot}56$

Cals. for the crystalline salt, and 300·04 for the fused salt; and 305·29 Cals. for the salt in soln. H. Giran gave respectively 305·83, 303·32, and 308·53 Cals. A. Joly gave for $P_2O_5+H_2O_{solid}=P_2O_5.3H_2O+29\cdot6$ Cals.; and H. Giran, for the **heat of hydration** of solid, liquid, and soln. of pyrophosphoric acid, $H_4P_2O_7$, with liquid. water to form respectively solid, liquid, and soln. $2H_3PO_4$, 6·97, 9·09, and 4·25 Cals. respectively. A. Joly gave for $P_2O_5.3H_2O_{solid}=P_2O_5.4H_2O_{solid}$(or $2H_3PO_4.H_2O$) $+3\cdot7$ Cals., $P_2O_5+4H_2O_{solid}=P_2O_5.4H_2O+33\cdot3$ Cals. G. Rümelin gave for the **heat of dilution** of soln. with 11·19, 13·88, 19·88, and 29·99 mols of water per mol of H_3PO_4, the respective values 33·13, 19·93, 12·26, and 8·23 Cals. respectively. P. A. Favre and J. T. Silbermann gave 323·9 cals. for the **heat of neutralization** of a gram of a dil. soln. of potassium hydroxide with orthophosphoric acid, and 480·1 cals. for sodium hydroxide. J. Thomsen found the heat of neutralization of a mol of phosphoric acid with a soln. of *n* mols of sodium hydroxide: $H_3PO_{4aq.}+nNaOH_{aq.}$

n	0·5	1·0	2·0	3·0	6·0
Heat of neutralization .	7·3	14·8	27·1	34·0	35·3 Cals.

M. Berthelot and W. Longuinine obtained rather smaller values. This shows that eq. proportions of sodium hydroxide have very different thermal values—the first equivalent 14·8 Cals., the second, not very different, 12·3 Cals., and the third 6·9 Cals. R. de Forcrand found the total value of the three acid functions of phosphoric acid: $H_3PO_{4aq.}+Na_{3aq.}=H_{3gas}+Na_3PO_{4aq.}+148\cdot13$ Cals., with a mean value for each 49·38 Cals. The observed value for the first is 60·6 Cals., for the second 49·2 Cals., and for the third, 38·83 Cals. The thermal value of the first acidic hydrogen is high because of intramolecular combinations; the second is less, showing that the displacement is more easily effected once the way has been opened; and similarly with the third. M. Berthelot obtained for the heat of neutralization of $n=1$ and $n=2$ mols of ammonium hydroxide with a mol. of phosphoric acid respectively 13·5 and 26·3 Cals.; while for the hydroxides of the alkaline earths, by the dissolution of a mol. of H_3PO_4 in six litres of water at 16°, and 0·5CaO, CaO, and 1·5CaO, 14·8, 24·5, and 29·8 Cals. respectively; with strontium oxide similarly, 15·05, 25·3, and 30·3 Cals.; and with barium oxide, 15·0, 25·4, and 30·4 Cals. P. Tutoit and E. Grobet measured the temp. of the soln. during the progressive neutralization of phosphoric acid and obtained three characteristic breaks. O. Stelling studied the **X-ray spectrum.**

J. Thomsen gave for the **heat of solution** of a mol. of the crystalline acid, 2·69 Cals.; and of the liquid acid, 5·21 Cals. A. Joly gave for $P_2O_5.3H_2O_{solid}$ in 400 mols. of water at 13°, 5·34 Cals.; for $P_2O_5.4H_2O_{solid}$, 0·28 Cal.; and $P_2O_5.4H_2O_{liquid}$, 7·56 Cals.; for $P_2O_5.4H_2O+1700H_2O$, 0·62 Cal.; for $P_2O_5.4H_2O+260H_2O$, 0·16 Cal.; for $P_2O_5.4H_2O+200H_2O$, 0 Cal.; and for $P_2O_5.4H_2O+160H_2O$, —0·14 Cal. E. Petersen has measured the heat of dilution; and E. Bose, the heat of mixing. P. A. Favre and J. T. Silbermann find the thermal eq. of $H_3PO_4 : H_3PO_3 : H_3PO_2$ are related as 4·36 : 2·91 : 1. J. C. Thomlinson made some calculations on the heat of formation of the acids of phosphorus on the assumption that phosphorus is quadrivalent. S. Arrhenius gave for the **heat of ionization** per mol.: $H_3PO_4=H^{\cdot}+H_2PO'_4$ —1·82 Cals. at 35°, and —1·53 Cals. at 21·5°. The negative value of the heat of ionization is supposed to explain why the heat of neutralization exceeds 13·5 Cals., the normal value for the stronger acids. If Q denotes the heat of neutralization, q the heat of ionization, and a the degree of ionization, $Q=13\cdot52-(1-a)q$. At 2·15°, $a=0\cdot2$; $(1-a)q=-1\cdot242$; Q calculated $=15\cdot06$, observed $=14\cdot98$ Cals. At 35°, $a=0\cdot177$; $(1-a)q=-1\cdot5006$; $Q=14\cdot75$.

E. Cornec[16] gave 1·3507 for the **index of refraction** of the acid soln. of sp. gr. 1·1056. J. H. Gladstone found for the refractive index of soln. of sp. gr. 1·180 at 7·5°, 1·3584, 1·3630, and 1·3746 respectively for the *A*-, *D*-, and *H*-lines. W. J. Pope gave 21·6 for the refraction equivalent of the H_2PO_4-radicle. C. Féry said that in the progressive neutralization of phosphoric acid by sodium hydroxide there are three critical points corresponding with the appearance of the primary, secondary, and tertiary phosphates. E. Cornec found that with potassium hydroxide, there is evidence of the formation of the normal salt and of the dihydrophosphate as shown in Fig. 42, which also includes values for the refraction, $(\mu-1)/D$, and for the sp. gr. D. The results are thought by E. Cornec to be not inconsistent with the formation of complex phosphates, $KH_5(PO_4)_2$; $K_5H_4(PO_4)_3$; and $K_7H_5(PO_4)_4$. When ammonia is used in place of the alkali-lye, the normal and dihydro-salts produce singular points on the curve. J. A. Wasastjerna studied the refraction equivalents of the phosphates. W. W. Coblentz found orthophosphoric acid to be too opaque to obtain other than an imperfect **ultra-red transmission spectrum.**

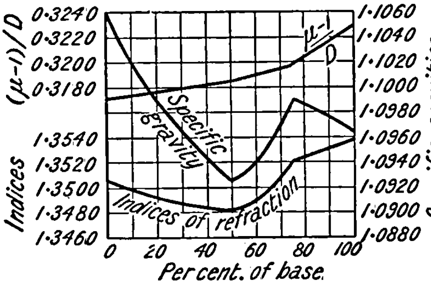

FIG. 42.—Neutralization Curves of Phosphoric Acid.

J. F. Daniell[17] electrolyzed a 6 to 11 per cent. soln. of phosphoric acid in a cell with electrode compartments and obtained the migration value $n=\frac{1}{4}$. M. Faraday tried to electrolyze molten phosphoric acid, but he obtained evidence that only the adsorbed water was decomposed by the current, not the acid itself. Again, according to C. Luckow, aq. soln. of phosphoric acid are not decomposed by the electric current, but if carbon electrodes be employed, A. Bartoli and G. Papasogli say that *phosphomellogen* is formed, and with graphite electrodes, *phosphographitic acid.* According to G. Janecek, when molten phosphoric acid is electrolyzed at a temp. below that at which it begins to lose water, it first forms pyrophosphoric acid, then metaphosphoric acid, then phosphorous acid and phosphine.

According to M. Rabinowitsch,[18] the **electrical conductivity** of orthophosphoric acid, $2H_3PO_4.H_2O$, in the crystalline and surfused states approximates respectively to 10^{-4} and 10^{-2} mhos. The temp. coeff. is positive, and there is an abrupt change on solidification. The decomposition potential is 1·70 volts. The ratio of the electrical conductivities in the crystalline and surfused states is assumed to indicate the degree of loosening of the crystal lattices. The conductivity of the anhydrous acid decreases with time, and is associated with some change in the acid. W. Ostwald found the electrical conductivity of phosphoric acid to be 7·27 when that of hydrochloric acid is 100. The specific and eq. electrical conductivity of soln. of phosphoric acid has been measured at 18° by F. Kohlrausch. The conductivity of soln. of phosphoric acid has also been measured by W. Foster, A. A. Noyes and co-workers, W. Ostwald, C. Déguisne, S. Arrhenius, H. Compton, F. W. Küster and co-workers, D. Berthelot, A. Smith and A. W. C. Menzies, E. B. R. Prideaux, M. Pouchon, H. Wegelins, and G. A. Abbott and W. C. Bray. H. E. W. Phillips used highly purified phosphoric acid and obtained the results indicated in Table V. These are plotted in Fig. 44, along with those for hydrochloric, nitric, and sulphuric acids and for soln. of potassium and sodium hydroxides for comparison. The conductivity of phosphoric acid thus increases with concentration from 1·4 to 38 per cent.; thence to 44 per cent. the increase is slow; it then decreases slowly to about 50 per cent., after which the decrease is as rapid as the former rise. H. Crompton found that the second differential coeff. of the electrical conductivity with the composition of the soln. indicated the presence of $H_3PO_4.7H_2O$ and of $H_3PO_4.2H_2O$—*vide* sulphuric acid. S. Arrhenius found a maximum in the conductivity, λ, with variations of temp. θ. The temp. effect can be represented by $\lambda=\lambda_0e^{-0\cdot0822\theta}(1+0\cdot01455\theta)$,

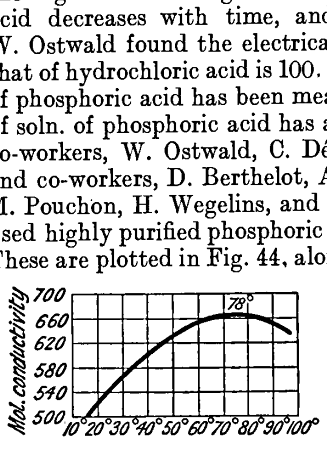

FIG. 43.—The Effect of Temperature on the Electrical Conductivity of Solutions of Phosphoric Acid.

TABLE V.—ELECTRICAL CONDUCTIVITIES OF SOLUTIONS OF PHOSPHORIC ACID.

Percentage concentration.	Equivalents per litre.	Specific resistance.	Specific conductivity.	Molecular conductivity.	Percentage ionization.
1·4	0·43	71·435	0·01400	97·50	40·63
2·87	0·89	39·484	0·02533	85·20	35·50

100·03	57·69	71·134	0·01406	1·73	0·30

which is a maximum when $\theta=53°$, but since the conductivity at λ_0 is taken at 25°, the maximum, as in Fig. 43, occurs at 78°. The percentage ionization is also shown in Table V. A. A. Noyes and co-workers found the effect of temp. on the conductivity to be such that for soln. containing M milli-formula weights of H_3PO_4 per litre, the conductivities were as follow :

M	18°	25°	50°	75°	100°	128°	156°
0·0	338	376	510	631	730	839	930
0·2	330·8	367·2	493·0	600·3	688·5	762·1	804·7
2·0	283·1	311·9	400·7	463·6	498·2	507·6	489·0
10·0	203	222	273	300	308	298	274
12·5	191·2	208·1	254·1	278·5	283·9	273·6	250·5
50·0	122·7	132·6	157·8	168·6	167·8	158·0	142·0
80·0	104	112·4	133	141	141	134	118
100·0	96·5	104·0	122·7	129·9	128·4	120·2	107·87

The temp. coeff. is negative at the higher temp. and positive at the lower temp.; this also agrees with the observations of A. N. Campbell on the conductivity of phosphoric acid at 0°, and those of F. Kohlrausch at 18°. A. A. Noyes and co-workers calculated that the percentage **ionization**, a, of soln. of phosphoric acid when the conc. are expressed in milli-formula-weights per litre at 4°.

Conc.	0·0	0·2	2·0	10·0	12·5	50·0	80·0	100·0
a 18°	100	98	84	60	36·5	36·5	31·0	38·5 per cent.
a 156°	100	86·5	52·5	29·4	27·0	15·5	12·5	11·5 ,,

J. Kendall and co-workers also computed values of a from the cryoscopic data. Phosphoric acid is a comparatively weak acid which ionizes in three stages: $H_3PO_4 \rightleftharpoons H^{\cdot}+H_2PO'_4 \rightleftharpoons 2H+HPO_4''$, at moderate dilutions, and even at extreme dilutions it is but partially resolved: $H_3PO_4 \rightleftharpoons 3H^{\cdot}+PO_4'''$. The first hydrogen ion has the strongest acidic function, the third the weakest. G. A. Abbott and W. C. Bray have also measured the ionization constants of orthophosphoric acid and find at 18°:

$H_3PO_4 \rightleftharpoons H^{\cdot}+H_2PO_4'$ . . . . . $K_1=1{\cdot}1\times10^{-2}$
$H_2PO'_4 \rightleftharpoons H^{\cdot}+HPO_4''$ . . . . . $K_2=1{\cdot}95\times10^{-7}$
$HPO''_4 \rightleftharpoons H^{\cdot}+PO_4''$ . . . . . . $K_3=3{\cdot}6\times10^{-13}$

For comparison, the results with carbonic acid and hydrogen sulphide are quoted:

$H_2CO_3 \rightleftharpoons H^{\cdot}+HCO_3'$. $K_1=3{\cdot}0\times10^{-7}$ $H_2S \rightleftharpoons H^{\cdot}+HS'$ . . $K_1=9{\cdot}1\times10^{-8}$
$HCO'_3 \rightleftharpoons H^{\cdot}+CO_2''$. $K_2=6{\cdot}0\times10^{-11}$ $HS' \rightleftharpoons H^{\cdot}+S''$ . . $K_2=1{\cdot}2\times10^{-15}$

M. S. Sherrill and A. A. Noyes gave $K_1=0{\cdot}0083$ when expresssed in terms of the activities at 18°. E. B. R. Prideaux gave for K_2, $1{\cdot}95\times10^{-7}$, and for K_3,

$3{\cdot}0\times10^{-12}$; H. T. S. Britton, $K_1=0{\cdot}0094$; $K_2=1{\cdot}4\times10^{-7}$; and $K_3=2{\cdot}7\times10^{-13}$; E. Blanc, $K_2=8\times10^{-7}$; and $K_3=2{\cdot}3\times10^{-12}$; while E. B. R. Prideaux and A. T. Ward gave $K_2=6\times10^{-8}$, and $K_3=1{\cdot}1\times10^{-12}$. C. Matignon, and G. Gire gave $K_2=1{\cdot}9\times10^{-7}$; and E. Blanc, $K_2=2\times10^{-5}$. I. M. Kolthoff calculated $K_3=5\times10^{-13}$. The ionization constants were also studied by L. V. Rothmund and K. Drucker, A. A. Noyes, and G. W. Eastman, and J. Kendall and co-workers. Hence, orthophosphoric acid behaves like a fairly strong acid with respect to the first eq. of hydrogen; and like a weak acid intermediate between carbonic acid and hydrogen sulphide with respect to the second eq. of hydrogen; and like a very weak acid intermediate between HCO'_3 and HS′ with respect to the third eq. of hydrogen. In the normal phosphates, the third eq. of a base is so feebly combined that it can be displaced even by the dilution of the soluble phosphate with water; normal ammonium phosphate is particularly unstable. E. Blanc obtained the conductivity of a soln. of normal sodium phosphate treated with successive additions of hydrochloric acid and obtained a curve with breaks at $C_H=1{\cdot}1\times10^{-12}$, 4×10^{-11}, and $6{\cdot}5\times10^{-9}$. L. Pessel found that mixture of pyrophospboric and hydrochloric acids show an abnormally low electrical conductivity corresponding with a feebly ionized compound of the two acids; while J. Meyer and A. Pawletta observed that the conductivity of phosphoric acid remains the same with the progressive addition of sulphuric acid, while that of sulphuric acid remains the same with increasing concentration. H. C. Jones and co-workers calculated from the conductivity and f.p. data that in soln. containing M mols of phosphoric acid per litre, the ions are hydrated so that H mols of water are in combination with a mol of the salt at the given concentration:

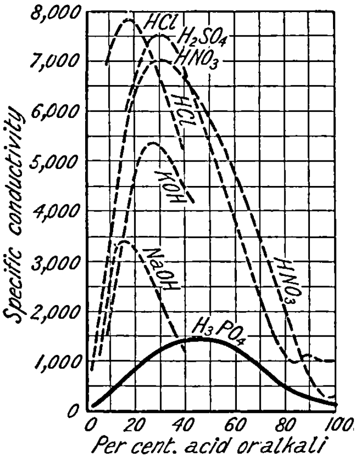

FIG. 44.—Electrical Conductivities of Solutions of Some Acids and Alkalies.

M . .	3·0	4·0	5·0	6·0	6·919
H . .	0·79	2·79	3·95	4·37	4·34

F. H. Jeffery observed that in the electrolysis of 15 per cent. orthophosphoric acid with a gold anode, a little of that metal passes into soln. For the affinity constant, *vide* sulphuric acid.

D. Berthelot showed that when a monobasic acid is treated with progressively increasing amounts of alkali, the electrical conductivity decreases to a minimum which is reached when the acid is neutralized by the base; any further addition of alkali causes the conductivity to increase. This is in agreement with the fact that the conductivity of a salt is in general less than that of its component acid or base. With polybasic acids, a minimum occurs when enough alkali has been added to form a primary salt, the conductivity then increases, and then increases in passing from the primary to the secondary, and from secondary to tertiary salts. The first hydrogen of phosphoric acid was found to behave like a monobasic acid; the second hydrogen, like a slightly ionized weak acid; and the third hydrogen, like the OH-radicle of phenol. These facts agree with the heats of neutralization; the lowering of the f.p.; sp. gr. of soln.; the indices of refraction, and with the behaviour of the acid towards indicators where R. T. Thomson, and E. Salm showed that one eq. may be titrated with methyl-orange as indicator; the second with phenolphthalein, and the third with trinitrobenzene as indicator. Phosphoric acid thus appears to be monobasic with methyl-orange as indicator; dibasic with phenolphthalein, and tribasic with trinitrobenzene. F. W. Küster and co-workers determined the neutralization points of phosphoric acid from conductivity measurements. The curve given by W. M. Clark shows the **hydrogen ion concentration** during the process of the titration of 50 c.c. of 0·1M-H_3PO_4 with 0·1N-KOH. Methyl-orange is sensitive to H˙-ions over the range 3·1 to 4·4p_H, and phenolphthalein, over the range 8·3 to 10·0p_H, and these indicators are therefore applicable for the KH_2PO_4 and K_2HPO_4 stages respectively as shown in the diagram. C. E. Davis and co-workers, W. F. Hoffmann and R. A. Gortner, J. C. Brünnich, and R. Dubrisay formed similar conclusions. W. E. Ringer measured the H˙-ion conc. of dil. soln. of phosphoric acid and of sodium hydrophosphate, and dihydrophosphate. W. F. Hoffmann and R. A. Gortner, K. Täufel and C. Wagner, and G. L. Wendt and A. H. Clarke studied the electrometric titration with calcium hydroxide; and H. T. S. Britton, the electrometric titration of the acid with sodium hydroxide and the alkaline earth hydroxides, as well as of trisodium phosphate soln. with soln. of salts of calcium, beryllium, magnesium, zinc, aluminium, zirconium, thorium, chromium, and manganese. The activity of the phosphate ions was discussed by E. J. Cohn.

The temp. coeff. of the conductivity was measured by F. Kohlrausch, D. Berthelot, S. Arrhenius, and C. Déguisne. For a 10 per cent. soln., when the sp. conductivity at 18° is represented by K_{18}, the temp. coeff. $(dK/dT_{22})/K_{18}$ is 0·0104; for a 50 per cent. soln., 0·0174; and for an 87·1 per cent. soln., 0·0372. A given soln. has a definite temp. for the maximum conductivity, and above that temp., the conductivity decreases. The increasing mobility of the ions with rise of temp. may be compensated by the decreasing ionization. A. A. Noyes found for a 3×0·98 mol. soln., at 12°, 76°, and 93°, respectively, the mol. conductivities 50·2, 71·0, and 69·4 with the temp. coeff. 0·60, 0, and —0·12 respectively. The negative temp. coeff. corresponds with the negative heat of ionization.

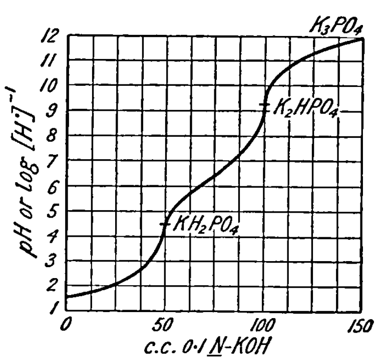

FIG. 45.—The Hydrogen Ion Concentration during the Titration of Phosphoric Acid with Alkali-lye.

W. Plotnikoff found the mol. conductivity of ethereal soln. diminishes with dilution, and increases with rise of temp. W. Hittorf attempted to determine the **transport number** of the anion in aq. soln. of normal sodium phosphate, but the salt was so much hydrolyzed that most of the current was carried by the alkali. With aq. soln. of sodium hydrophosphate, the transport number of the HPO''_4-anion was 0·516; and with sodium dihydrophosphate for the $H_2PO'_4$-anion, 0·383. J. F. Daniell and W. A. Miller also made some observations with this salt. W. Hittorf found with soln. of potassium dihydrophosphate, the transport number of the $H_2PO'_4$-anion was 0·277. O. Wosnessensky measured the potential difference at the boundary of phosphoric acid and a non-aqueous solvent. P. Pascal studied the magnetic properties. J. Murray tried if he could decompose a soln. of the acid by magnetized iron.

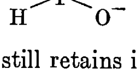
The constitution of phosphoric acid.—The analyses of phosphoric acid by E. M. Péligot,[19] R. Brandes, M. Berthelot, and A. Joly correspond with the hemihydrate. A. Hantzsch found that in sulphuric acid soln. the depression of the f.p. for soln. of different conc. corresponded with mol. wts. ranging from 54 to 78, and therefore, said he, orthophosphoric acid is very strongly ionized in this solvent. On the other hand, according to H. Giran, the f.p. in glacial acetic acid shows that the mol. wt. of orthophosphoric acid in a freshly prepared soln. corresponds with that required for $(H_3PO_4)_2$, but soon approaches that required for H_3PO_4. This phenomenon recalls F. M. Raoult's observation that the mol. wts. of freshly prepared soln. of sulphuric and hydrochloric acids in acetic acid correspond respectively with $(H_2SO_4)_2$ and $(HCl)_2$, and that the molecules depolymerize on standing. Acetic acid, also, has simple molecules CH_3COOH in aq. soln., and doubled molecules $(CH_3COOH)_2$ in benzene soln. D. Balareff found that soln. of ortho- and meta-phosphoric acids slowly form pyrophosphoric acid; and he showed that the vap. densities of methyl and ethyl phosphates agree with the normal values for R_3PO_4. The structural formula for phosphoric acid will depend upon what view is adopted about the valency of phosphorus—ter- or quinquevalent. In the former case, the structural formula will be $HO—O—P{=}(OH)_2$, and $O{=}P{\equiv}(OH)_3$ in the latter. The first formula was suggested by J. Thomsen to explain the peculiar thermal phenomena attending the progressive addition of sodium hydroxide to the acid. The hypothesis is unnecessary since it is more probable that with the three hydrogen atoms the one helps the other in such a way that if one be removed the bonds holding the other two are weakened. P. Pascal also said that the magnetic susceptibilities favour the $PO(OH)_3$ formula for phosphoric acid and $R—PO(OH)_2$ for *phosphinic acid*. The first formula is generally preferred for the following reasons: Phosphoryl chloride must be either $Cl—O—P{=}Cl_2$ or $O{=}P{\equiv}Cl_3$. Phosphorus is undoubtedly quinquevalent in the pentafluoride and also in the pentachloride. From the mode of formation of phosphoryl chloride the formula $O{=}PCl_3$ is usually considered, without direct proof, to be more probable. Phosphoric acid is formed by treating phosphoryl chloride, $O{=}PCl_3$, with water, and therefore $O{=}P{\equiv}(OH)_3$ is the most probable structural formula for phosphoric acid. G. Oddo made an hypothesis in which it is assumed that an atom of hydrogen, in the neighbourhood of two multi-valent elements, can divide its valency between the two by assuming a mean position of stable equilibrium; he symbolizes the valency $-\!\!<$; and calls the phenomenon *mesoidria—mesohydry*. The formula is in agreement with O. Stelling's observations on the *K*-series of the X-ray spectra. T. M. Lowry said that as in the case of the oxy-sulphur acids—*vide* hyposulphurous acid—the most stable acid of phosphorus contains four oxygen atoms. The PO_4'''-ion can be written:

$${}^{O^-}_{O^-}\!\!>\overset{+}{P}<^{O^-}_{O^-}$$

where the atom of phosphorus carries a single positive charge. The corresponding acid with three negatively-charged oxygen atoms is of low stability, being only dibasic:

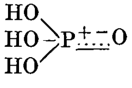
$${}^{H}_{O^-}\!\!>\overset{+}{P}<^{O^-}_{O^-}$$

while hypophosphorous acid with only two negatively-charged oxygen atoms is monobasic:



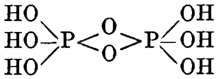
$${}^{H}_{H}\!\!>\overset{+}{P}<^{O^-}_{O^-}$$

and the central phosphorus atoms still retains its positive charge, for this appears to be a necessary condition for stability with nearly all the oxy-acids. H. Burgarth, and H. Remy discussed this subject. E. B. R. Prideaux gave for the electronic structure (*vide infra*, phosphorus pentachloride):



$$\begin{matrix}HO\\HO\\HO\end{matrix}\!\!>P\underset{\cdots}{\overset{+\ -}{}}O$$

The basicity of phosphoric acid appears different when it is neutralized with sodium hydroxide according to the indicator employed—*vide supra*—and the electrical conductivity data explain how the acid was once considered by M. Berthelot and W. Louguinine, A. Joly, D. Berthelot, P. Walden, and J. B. Senderens to be dibasic like sulphuric or oxalic acid, and not tribasic like citric acid. Indeed, there is now little room for doubting the tribasicity of the acid, and E. Cornec's f.p. curves for mixtures of phosphoric acid with different proportions of sodium hydroxide give a minimum for Na_3PO_4, and two folds representing the formation of Na_2HPO_4, and NaH_2PO_4, Fig. 42. If the doubled formula for phosphoric acid —$(H_3PO_4)_2$, that is, $H_6P_2O_8$—be accepted, this acid probably has the constitution:



The doubled formula corresponds (i) with H. Giran's value for the mol. wt. of the acid in acetic acid soln.; (ii) with the formation of A. Joly's hemihydrate, $2H_3PO_4.H_2O$; (iii) with D. Balareff's measurements of the vap. press. of soln. of the ortho-acid on a rising temp. where a marked rise of temp. occurs when the acid dissociates to simple molecules: $(H_3PO_4)_2=2H_3PO_4$; and (iv) with H. Giran's series of salts of the type $M'H_5P_2O_8$; and with E. Filhol and J. B. Senderens salts of the type $M'''H_3P_2O_8$, that is, $M'''PO_4.H_3PO_4$. D. Balareff said that orthophosphoric acid is partly converted into the pyro-acid when kept in a desiccator over phosphoric oxide, or even over sulphuric acid. Orthophosphoric acid has the simple mol. wt. in sulphuric acid soln., and if the free acid had the same constitution, it might be expected that the pyro-acid would also be formed on dissolving in sulphuric acid, but this is not the case. Ethyl and methyl orthophosphates have vapour densities corresponding approximately with the simple formulæ.

According to A. Werner's hypothesis, the molecule of phosphoric acid consists of an atom of phosphorus co-ordinated with four oxygen atoms in accord with the co-ordination number of that element. This group forms the tervalent anion of tribasic phosphoric acid:

$\left[\begin{matrix}\text{O}\\ \text{OPO}\\ \text{O}\end{matrix}\right]^{'''}\text{H}^{\cdot}_{3}$	$\left[\begin{matrix}\text{O}\\ \text{OPH}\\ \text{O}\end{matrix}\right]^{''}\text{H}^{\cdot}_{2}$	$\left[\begin{matrix}\text{O}\\ \text{OPH}\\ \text{H}\end{matrix}\right]^{'}\text{H}^{\cdot}$	$\left[\begin{matrix}\text{H}\\ \text{OPH}\\ \text{H}\end{matrix}\right]$	$\left[\begin{matrix}\text{H}\\ \text{HPH}\\ \text{H}\end{matrix}\right]^{\cdot}\text{I}'$
Phosphoric acid.	Phosphorous acid.	Hypophosphorous acid.	Phosphine oxide.	Phosphonium iodide.

If one of the oxygen atoms be replaced by a hydrogen atom, the bivalent anion of dibasic phosphorous acid is formed; and if another oxygen atom be replaced by hydrogen, the univalent anion of monobasic hypophosphorous acid is formed. The substitution of a third hydrogen atom for an oxygen atom furnishes a neutral group corresponding with POH_3; this compound has not been isolated, but the methyl and ethyl derivatives, $(CH_3)_3PO$, and $(C_2H_5)_3PO$, have been prepared. The substitution of the remaining oxygen atom by hydrogen furnishes the phosphonium cation $PH^{\cdot}_4$. H. E. Armstrong and F. P. Worley made some observations on the constitution of phosphoric acid—*vide* sulphuric acid.

The action of heat on orthophosphoric acid.—In his *Recherches on the Arsenates, Phosphates, and Modifications of Phosphoric Acid*, T. Graham[20] showed that when evaporated at about 149°, a dil. soln. of phosphoric acid gives a syrupy liquid which consists entirely of orthophosphoric acid, and between 150° and 160°, it loses water very slowly. At 238°, it loses water so that the ratio is $P_2O_5 : H_2O = 1 : 2\frac{2}{3}$ instead of 1 : 3 required for the orthophosphatic acid. When evaporated slowly in a platinum flask between 212° and 213°, the ratio was reduced to $1 : 2\frac{1}{3}$ because a very large proportion is converted into pyrophosphoric acid, $H_4P_2O_7$. At the greatest heat of a sand-bath—considerably higher than the m.p. of lead—the proportion of water was reduced to a little less than 1 : 2, and the product consisted largely of meta-phosphoric acid. G. Tammann found that if orthophosphoric acid be heated until it begins to fume, pyrophosphoric acid is formed; and by further heating, there is obtained a liquid which, on cooling, forms a white fibrous mass of metaphosphoric acid. The conversion to pyrophosphoric acid, says G. Watson, is not complete between 230° and 235°, but is so between 255° and 260°; the formation of the meta-acid begins between 290° and 300°. The vap. press. measurements of D. Balareff show that orthophosphoric acid probably has the formula $(H_3PO_4)_2$, and when heated in a closed vessel, there is an equilibrium reaction, $(H_3PO_4)_2 \rightleftharpoons H_4P_2O_7 + H_2O$, and that with a rising temp. $H_4P_2O_7 \rightleftharpoons 2HPO_3 + H_2O$ occurs. In addition, there is the depolymerization: $(H_3PO_4)_2 \rightleftharpoons 2H_3PO_4$, and this is followed by $H_3PO_4 \rightleftharpoons H_2O + HPO_3$. D. Balareff's results for the vap. press. of the dehydrating orthophosphoric acid at different temp., and the formation of pyro- and meta-phosphoric acids are shown in Fig. 46. The volatility of the metaphosphoric acid prevented the completion of its curve, but sufficient remains to show that the reaction, $(H_3PO_4)_2 \rightleftharpoons H_4P_2O_7 + H_2O$, is reversible, and the proportion of pyrophosphoric acid formed at any given temp. is diminished by increasing the vap. press. of the water in the system. Similar remarks apply to the formation of metaphosphoric acid from the pyro-acid: $H_4P_2O_7 \rightleftharpoons H_2O + 2HPO_3$. The dissociation of the doubled molecule of the ortho-acid: $(H_3PO_4)_2 \rightleftharpoons 2H_3PO_4$, with rising temp. leads to the supposition that metaphosphoric acid might be produced directly from the ortho-acid: $H_3PO_4 \rightleftharpoons HPO_3 + H_2O$, but this reaction has not yet been demonstrated. According to M. Berthelot and G. André, during the dehydration of orthophosphoric acid, there is probably a state of equilibrium between the three acids—ortho-, pyro-, and meta-phosphoric acids—dependent upon the temp., so that if the temp. of dehydration is different, the product obtained by dissolving the calcined mass in water will be different. The action must be complex. For instance, when a mixture of meta- and orthophosphoric acids is heated (on a water-bath), the pyro-acid is formed: $HPO_3 + H_3PO_4 = H_4P_2O_7$.

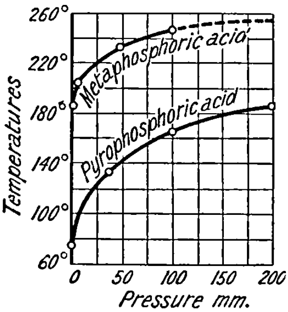


FIG. 46.—Vapour Pressures of Pyro- and Meta-phosphoric Acids.

J. J. Berzelius found that some acid is volatilized when phosphoric acid is heated in an open crucible, but not in a covered crucible, and H. Rose showed that in an open vessel all the phosphoric acid can be volatilized. J. B. Bunce said that some acid is volatilized with the steam, but G. C. Wittstein, and C. R. Fresenius showed that this is not the case when phosphoric acid is evaporated in an open dish, although some of the evaporating liquor may be carried away mechanically if the ebullition is rapid. E. Lautemann, S. Leavitt and J. A. Leclerc, and G. Lechartier have studied the loss of phosphoric oxide during the calcination of ash—about 2·14 per cent. was lost at low redness, 2·08 at bright redness. According to R. Bunsen, phosphoric acid is 23 times more volatile than sodium carbonate.

The chemical properties of orthophosphoric acid.—W. Müller-Erzbach[21] has discussed the affinity of the metals for phosphoric acid. J. Thomsen found the avidity of a mol. of phosphoric acid for one of sodium hydroxide to be a quarter of the value of that for hydrochloric acid. The affinity of phosphoric acid for the bases is greater than that of carbonic acid, boric acid, phosphorous acid, and hypophosphorous acid. The catalytic action of phosphoric acid on the reaction between bromic and hydriodic acids has been studied by W. Ostwald; on the reaction between iodic and sulphurous acids, by R. Höpke; and A. Purgotti and L. Zanichelli on hydrazine sulphate, $N_2H_4.H_2SO_4$. According to W. Ostwald, the velocity constant for the inversion of cane sugar by phosphoric acid is 6·21 when the value for hydrochloric acid is 100; and J. Spohr showed that the presence of neutral salts at 25° retards, or at 40° completely suppresses, the activity of phosphoric acid.

C. R. Fresenius observed no signs of reduction when phosphoric acid is heated in a stream of **hydrogen,** or if in the presence of hydrogen *in statu nascendi.* W. Ipatieff found that phosphoric acid is reduced to phosphorus at 350°–360°. According to W. Ipatieff and W. Nikolaieff, free phosphoric acid and its alkali salts are not affected by hydrogen under high press. and at an elevated temp., but ferric phosphate gives a series of crystalline complex phosphates: $Fe'''_nFe''_mPO_4.xH_2O$, depending on the conditions, and resembling the vivianites. Lead phosphate with hydrogen at 250 to 300 atm. and 360° to 400°, forms a colloidal, orange hemioxide, Pb_2O, and hypophosphorous acid, but with watergas at 400 atm., some phosphine, and lead are formed. The behaviour of soln. of phosphoric acid in **water** towards indicators has been discussed above —*vide* also Table VI. H. E. W. Phillips said that the 100 per cent. acid does not react with litmus. M. Berthelot and G. André found the partition coeff. of phosphoric acid between water and ether is such that the concentration in ether =2700 : 1, with a 8·33 per cent. aq. soln.; this ratio is 2900 : 1 with a 30 per cent. soln., with a very conc. soln. of phosphoric acid ether is attacked, forming a compound with the evolution of heat, and ether may be added in any proportion causing a precipitation. If a small quantity of water is added, it mixes completely, but if the addition of water is continued, there at last comes a point when a small quantity of ether separates, highly charged with phosphoric acid. The addition of more water causes the separation of a larger vol. of ether containing a lower proportion of acid, and still more water separates a still larger vol. of ether containing still less acid, and this change continues as the addition of water is continued, until the partition coeff. already stated is reached. D. Balareff observed that a soln. of orthophosphoric acid slowly forms pyrophosphoric acid on keeping. According to W. F. Hillebrand and G. E. F. Lundell, no volatilization losses of phosphorus occur during evaporation of sulphuric acid soln. of phosphates, provided the evaporation is carried on at 150° and stopped when fumes appear. Volatilization losses of phosphorus from sulphuric acid soln. of phosphates may occur during evaporation to complete expulsion of sulphuric acid, during evaporation at high temperatures, such as 200°–260°, and by unduly prolonged evaporation above 150°. M. Berthelot and G. André did not observe any signs of reduction when phosphoric acid is heated with **acids** at 100°. According to F. Flichter and W. Bladergroen, soln. of phosphoric acid, after treatment with fluorine, immediately precipitate iodine from iodides. A slight additional precipitate occurs in one or two cases on keeping. The oxidizing power is attributed principally to permonophosphoric acid, H_3PO_5. The soln., and also permonophosphoric acid prepared by the action of hydrogen peroxide on phosphorus pentoxide, oxidized manganous sulphate to violet manganic phosphate, and not to permanganate as suggested by J. Schmidlin and P. Massini. The action of fluorine on di- or tri-alkali phosphates and on pyrophosphates, produced salts of both permonophosphoric acid and perphosphoric acid, $H_4P_2O_8$ (precipitated in two stages); the former is unstable, so that it was possible to obtain perphosphoric acid mixed with potassium fluoride from the soln. If **hypochlorites** are evaporated with conc. phosphoric acid, A. J. Balard said that hypochlorous acid and some chlorine are formed; as well as a little chloride. P. Chrétien prepared a complex with **iodic acid,** namely, *phosphatoiodic acid,* $P_2O_5.18I_2O_5.4H_2O$, in needle-like crystals by boiling syrupy phosphoric acid with an excess of iodic acid. The product is rapidly decomposed by moist air. Fine crystals of ammonium phosphatoiodate, $4(NH_4)_2O.P_2O_5.18I_2O_4.12H_2O$; lithium phosphatoiodate, $3Li_2O.P_2O_5.11H_2O$; sodium phosphatoiodate, $6Na_2O.P_2O_5.18I_2O_5.5H_2O$; and potassium phosphatoiodate, $4K_2O.18I_2O_5.5H_2O$, were obtained by adding iodic acid, in small portions at a time, to boiling syrupy phosphoric acid in which the alkali dihydrophosphate had been dissolved, and slowly cooling to liquid.

P. N. Raikow found that phosphoric acid dissolves **sulphuric acid** at ordinary temp., and when the soln. is heated to 350° some sulphur dioxide is evolved. The phosphates are all decomposed by treatment with sulphuric acid. R. H. Adie, and C. Friedheim prepared complex compounds of sulphuric and phosphoric acids —*vide infra,* phosphoryl hydrosulphate. H. Prause prepared complexes with **telluric acid**—*e.g.* $(NH_4)_4P_2TeO_{10}$. H. Reinsch found that syrupy phosphoric acid absorbs **nitric oxide,** and forms a crystalline mass when cooled to —20°; the product may be a compound. According to E. Divers, phosphoric acid does not act very vigorously on a soln. of **ammonium nitrate** in ammonia. F. D. Chattaway and H. P. Stevens found that phosphoric acid decomposes **nitrogen iodide,** producing ammonia. According to A. Geuther, when phosphoric acid is treated with **phosphorus pentachloride** at ordinary temp., phosphoryl chloride and hydrogen chloride are formed; **phosphorus trichloride** furnishes metaphosphoric and phosphorous acids; and **phosphoryl chloride** is without action in the cold, but when hot, metaphosphoric acid is formed if the phosphoryl chloride be in excess, and phosphorous acid if only a little be present. G. Meyer, and A. Vogel prepared a complex with **boric oxide** or **boric acid**—*vide* boron phosphate, **5**. 32, 27.

When heated with **carbon,** the phosphates of the heavy metals are generally changed into phosphides; the phosphates of the alkali and alkaline earth metals are not decomposed except at temp. exceeding 1200°—*vide supra,* the preparation of phosphorus. M. Dubinin studied the adsorption of phosphoric acid by carbon; P. Carré, the action of phosphoric acid on **alcohol**; J. Heimann, on **cetyl alcohol**; A. Benrath, on **sodium ethoxide**; P. N. Raikow and P. Tischkoff, on **esters**; M. Berthelot and G. André, and M. Rabinowitsch and S. Jakubsohn, on **ether**; P. Carré, on **glycol**; and H. Imbert and G. Belugou, P. Carré, G. Prunier, L. A. Adrian and J. A. Trillat, A. Contardi, F. B. Power and F. Tutin, on **glycerol.** If glacial phosphoric acid and glycerol be heated to 100°, the product neutralized with barium carbonate, and the filtered soln. decomposed with the calculated amount of sulphuric acid, *glycerophosphoric acid,* $CH_2OH.CHOH.CH_2O.PO(OH)_2$, is formed. This acid forms normal and acid salts with the metals, and combines with organic bases like quinine. O. Meyerhof and J. Suranyi measured the ionization constants of glycerophosphoric, and hexosediphosphoric acid; and P. Fleury and Z. Sutu, the hydrolysis of the α- and β-glycerophosphoric acids. W. Ostwald, J. Spohr, and J. R. Duggan investigated the action of phosphoric acid on **sugars**; L. Portes and G. Prunier, and P. Carré, on **mannitol**; P. Carré, on **erythritol**; P. N. Raikow and R. Tischkoff, on **sulphanilic acid,** and **sulphosalicylic acids**; C. Friedel and J. M. Crafts, on **aromatic sulpho-acids**; D. Vorländer and A. J. Perold, on **wool**; W. W. Worms, A. A. Panormoff, and G. S. Johnson, on **albumin**; and W. Reidemeister, on **agar-agar.** If phosphoric acid or a phosphate be treated in the presence of carbonaceous matters, some phosphoric oxide may be lost. According to P. L. Dulong, and A. J. Balard, if phosphoric acid be heated in **porcelain** crucibles, the glazing is strongly attacked, and the acid so contaminated with alkali, silica, and alumina; if **platinum** crucibles are used, and organic matter or other reducing agents be present, the acid may be reduced and the phosphorus which is liberated will form an easily fusible phosphide with the metal. This may occur during the calcination of phosphatic precipitates —*e.g.* magnesium pyrophosphate—as shown by W. C. Heraeus, and W. P. Headdon. F. Mylius found that phosphoric acid attacks **quartz** vessels above 300°. P. Hautefeuille and J. Margottet found that **silica** dissolves fairly readily in phosphoric acid—about 5 per cent. at 260° —*vide* **6**. 40, 57; O. Nielsen made a partial examination of the ternary system, CaO–SiO_2–P_2O_5; and G. Saring prepared a series of complex salts of the type $Ca_3(PO_4)_2(CaO)_2(K_2O)_2SiO_2$, with the SiO_2 replaced by TiO_2, ZrO_2, CeO_2, ThO_2, SnO_2, PbO_2, $\frac{1}{2}B_2O_3$, $\frac{1}{2}Al_2O_3$, $\frac{1}{2}V_2O_3$, and MoO_3. P. Hautefeuille and J. Margottet prepared complexes with **titania, zirconia,** and **stannic oxide.** E. Wedekind and H. Wilke studied the adsorption of phosphoric acid by zirconia gels; and H. von Euler and E. Erikson, by **alumina** gel. K. Hüttner has studied the action of phosphoric acid on different **silicates.**

According to P. Thénard, and L. N. Vauquelin, when heated with **potassium** or **sodium,** the phosphates furnish alkali phosphides (*q.v.*). W. Smith reported that conc. or dil. phosphoric acid attacks **aluminium** with the evolution of hydrogen; H. Beyers and M. Darrin have studied the passivity of **iron** in phosphoric acid;

and F. Clarkson and H. C. Hetherington the corrosion of iron by the acid. T. Byrom found that **ferrosilicon, spiegeleisen, ferrochrome, ferrotitanium, ferromanganese, ferrovanadium, titanium nitride,** and **chromite** are dissolved by phosphoric acid of sp. gr. 1·75; and M. Wunder and B. Janneret found finely-divided **silicon** is dissolved in a few hours by phosphoric acid, sp. gr. 1·75, at 230°; **zirconium** is dissolved in a few minutes; **tungsten** takes a little longer; and **carborundum** is entirely decomposed in about three hours, while the carbon in these alloys remains undissolved. M. Berthelot found that phosphoric acid reacts with **potassium chromate:** $2H_3PO_4+2K_2CrO_4=2KH_2PO_4+K_2Cr_2O_7+H_2O+3\cdot42$ Cals. at 8°; P. Sabatier also found that chromates are almost completely decomposed by phosphoric acid; and C. Friedheim prepared complexes of **chromic acid** and phosphoric acid. Complexes are also obtained with **tungstic, molybdic, and vanadic acids.** P. Hautefeuille and J. Margottet found that at 100°, phosphoric acid dissolves about 15 per cent. of **ferric oxide,** or 8 per cent. of **alumina,** and if the soln. be maintained at this temp. for some time, crystals of the phosphates separate out. The insoluble phosphates are decomposed, wholly or in part, by fusion with **sodium carbonate.** H. E. W. Phillips said that the 100 per cent. acid does not react with sodium carbonate. W. C. Taber has investigated the solubility of **calcium sulphate** in phosphoric acid; J. Stoklasa, the action of phosphoric acid on **calcium phosphate;** and M. Berthelot, and A. Benrath, on **alkaline earth chlorides.** F. de Lalande and M. Prud'homme noticed the evolution of chlorine when phosphoric acid is heated with **sodium chloride.** M. Weilandt studied the action on the **alkaline earth carbonates,** A. Quartaroli, C. Blarey, A. Joly, and M. Berthelot, the action on the **alkaline earth oxides and hydroxides,** and **magnesia.** S. Bodforss studied the electrometric titration of phosphates with a soln. of a **uranyl** salt.

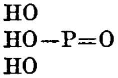
J. T. Meckstroth [22] showed that the largest use for phosphoric acid is in sugar defecation. It is also used in the manufacture of jellies, preserves, and soft drinks; in pharmaceutical preparations; and in the rust-proofing of iron. The chief phosphates in industry are the calcium hydrophosphates used in making baking-powder, and self-rising flour; sodium phosphates used in making boiler compounds, in laundry work, etc. The superphosphates are used in fertilizers. Calcium orthophosphate is the form of bone ash extensively used in the manufacture of bone china.

The physiological action of the phosphoric acids.—The alkali phosphates have the remarkable property of nearly preserving their neutrality in the presence of relatively large amounts of acid. For if a little acid be added to a soln. of sodium hydrophosphate, with its $H^{\cdot}$-ion conc. of $0\cdot0_{12}36$(HCl unity), enough acid must be added to convert all the salt to the dihydrophosphate, with its $H^{\cdot}$-ion conc. of $0\cdot0_{6}2$, before the faint acidity of the dihydrophosphate is apparent; and conversely, enough alkali-lye must be added to a soln. of dihydrophosphate before the faint alkaline reaction of the hydrophosphate is apparent. All mixtures of the two salts are more nearly neutral than either alone. L. J. Henderson,[23] and others have discussed the bearing of these facts on the effect of acid on the protoplasm containing the hydrophosphates. The acid forms dihydrophosphate, and through the ready diffusibility of the dihydrophosphate, emphasized by R. L. Maly, the cells eliminate this phosphate which, entering the blood stream, passes out of the body through the kidneys. L. J. Henderson and co-workers added:

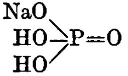
> It can hardly be doubted that the cell will endeavour to restore the normal ratio between potassium di- and mono-phosphates in view of the desirability of restoring the full normal power to neutralize acids. Moreover, though a considerable increase in the amount of phosphate at the expense of the other salt must involve a very slight changes in hydrogen ionization at most, even this slight change can hardly be without influence upon the delicate catalytic reactions of protoplasm. Moreover, too, slight changes of this sort probably influence the colloidal organization of protoplasm to a certain extent. Finally, it is clear that if acid is to be removed from protoplasm without preparatory chemical change it must leave in the form of potassium dihydrophosphate chiefly, for there can be no doubt that in this form chiefly it exists in protoplasm.

A. B. Poggiale [24] reported that dil. soln. of ortho-, pyro-, or meta-phosphoric acid are not poisonous, while conc. soln. behave like other strong acids. N. Sieber found that 0·5 per cent. hinders putrefaction, but fungi grow in the presence of a soln. of one per cent. of the acid. A. G. Salamon and W. de Vere Mathew found that large quantities of phosphoric acid hinder the growth of yeast. M. Paquelin and L. Jolly showed that pyrophosphates augment the flow of urine and act as diuretics. O. Schulz found that subcutaneous injections of phosphoric acid acted as a poison on rabbits. The subject was also studied by A. Desgrez and B. Guende, E. B. Hart and co-workers, M. Hayduck, M. Kochmann, P. Miquel, E. Moufang, and M. Rosenblatt and M. Rozenbrand.

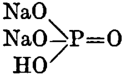
The orthophosphates.—Orthophosphoric acid forms three salts, normal or tertiary, secondary, and primary phosphates, according as all, two, or one of its hydrogen atoms is replaced by an equivalent radicle.[25] The hydrogen atoms may be replaced by different radicles. Thus, the secondary acid salt—ammonium sodium hydrogen phosphate, also called microcosmic salt—is illustrated by the subjoined graphic formula along with the formulæ for the acid and the primary, secondary, and tertiary sodium salts:



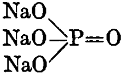
Orthophosphoric acid.

Primary.


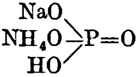
Sodium dihydrogen phosphate.

Secondary.


Disodium hydrogen phosphate.

Tertiary.


Normal sodium phosphate.

Secondary.


Microcosmic salt.

The tertiary alkali salts are strongly alkaline, the secondary salts are feebly alkaline, and the primary salts feebly acid. The behaviour of the sodium salts towards indicators, shown in Table VI, is interesting.

TABLE VI.—BEHAVIOUR OF SODIUM PHOSPHATES TOWARDS INDICATORS.

Sodium orthophosphate.	Methyl orange.	Phenolphthalein.	Litmus.	Porrier's blue.
Na_3PO_4 . . .	alkaline	alkaline	alkaline	neutral
Na_2HPO_4 . . .	alkaline	neutral	alkaline	neutral
NaH_2PO_4 . . .	neutral	acid	acid	acid

Orthophosphoric acid also forms three series of esters,[26] *e.g.*, **triethyl phosphate,** $(C_2H_5)_3PO_4$, or *phosphoric ether*, is a neutral liquid, insoluble in water; it boils at 215°, and has a sp. gr. 1·072, at 12°; the **diethyl phosphate,** $(C_2H_5)_2HPO_4$, or *diethylphosphoric acid*, acts as a monobasic acid; and **monoethyl phosphate,** $(C_2H_5)H_2PO_4$, or *ethylphosphoric acid* as a dibasic acid.

The orthophosphates are obtained by the direct action of the acid on the basic oxide, hydroxide, or carbonate; and the less soluble phosphates are obtained by double decomposition. While the soluble phosphates form tertiary, secondary, and primary phosphates, the tertiary phosphates of most of the heavy metals have been alone prepared. Consequently, tertiary phosphates are usually prepared by double decomposition—*e.g.* lead orthophosphate, $Pb_3(PO_4)_2$, is precipitated by mixing soln. of lead acetate and disodium hydrogen phosphate. Thallous phosphate and the phosphates of the alkali family of metals, with the exception of lithium, are soluble in water; the remaining phosphates are sparingly soluble, but are usually soluble in dil. nitric acid, and also in aq. soln. of the ammonium salts. The soluble tertiary and secondary phosphates usually have an alkaline reaction, and they can be distinguished by treating a soln. of the salt with calcium chloride, washing the precipitate with water, and warming it with aq. ammonia. A secondary phosphate is thus transformed into the tertiary salt. The phosphoric acid freed during the transformation of the $CaH(PO_4)_2$ will be found in the ammoniacal liquid; whereas, if the tertiary salt has been precipitated, no appreciable amount of phosphoric acid would be found in the ammoniacal liquid. The tertiary orthophosphates of the fixed bases are not decomposed by heat; but when a monohydrogen or secondary phosphate is heated, it forms a pyrophosphate and water; and when a dihydrogen or primary phosphate is heated, it forms a metaphosphate and water. The orthophosphates are described in connection with the individual elements.

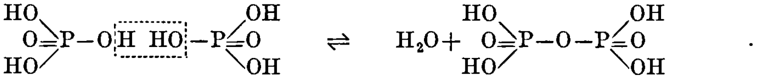
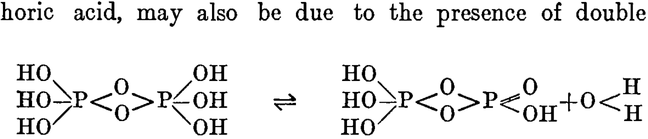
§ 25. Pyrophosphoric Acid

In 1828, T. Clark,[1] first prepared sodium pyrophosphate. He observed with surprise that with sodium phosphate specially purified by heat he obtained a white not a yellow precipitate with silver nitrate, and added, " it was natural to conjecture that sodium phosphate, in its ordinary state, contains some impurity to occasion the yellowness of the precipitate." He subsequently found that when he used sodium phosphate which had been dried at a red-heat, the white precipitate was occasioned by some alteration in the sodium phosphate which was produced by heat. The soln. of the salt which had been heated red hot gave a crop of crystals different in form from those obtained with ordinary sodium phosphate. These crystals were examined by W. Haidinger. He was then able to show that by simply drying the common sodium phosphate, and heating it to redness, an entirely new salt is produced, and added: " This new salt I shall call *pyrophosphate of soda*, a provisional name which it will probably be well to retain, till all doubts are removed respecting the constitution of this salt." Free acid and its salts were made by J. L. Gay Lussac in 1829; by F. Stromeyer in 1830; and by A. Schwarzenberg in 1847. As previously indicated in studying the action of heat on orthophosphoric acid, T. Graham, G. Tammann, G. Watson, and M. Berthelot and G. André obtained the pyro-acid by heating the ortho-acid between 250° and 260°. Two mols. of orthophosphoric acid lose one mol. of water, and the reaction has been graphically symbolized:



The formation of pyrophosphoric acid as the first product of the dehydration of orthophosphoric acid, may also be due to the presence of double molecules, $(H_3PO_4)_2$:



Orthophosphoric acid can thus be regarded as a hydrate, $H_4P_2O_7.H_2O$, of pyrophosphoric acid, and pyrophosphoric acid in turn as a hydrate of the meta-acid, in harmony with the view that pyrophosphoric acid is intermediate between ortho- and meta-phosphoric acids.

M. Berthelot and G. André did not obtain pyrophosphoric acid by heating the ortho-acid with acids at 100°; nor did E. B. R. Prideaux[2] obtain it by the action of an excess of water at room temp. on phosphorus pentoxide. A. Geuther, and A. Joly prepared pyrophosphoric acid by heating on a water-bath an aq. mixture of the two acids: $H_3PO_4+HPO_3=H_4P_2O_7$. F. Schwarz also made pyrophosphoric acid by heating triphosphoric acid with a small quantity of water: $2H_5P_3O_{10}+H_2O=3H_4P_2O_7$. According to A. Geuther, when an excess of phosphoric acid is treated with phosphoryl chloride, $POCl_3$, the pyro-acid is formed: $POCl_3+5H_3PO_4=3H_4P_2O_7+3HCl$; if the phosphoryl chloride be in excess, meta-acid, HPO_3, is formed: $POCl_3+2H_3PO_4=3HPO_3+3HCl$. Pyrophosphoric acid is also formed by the action of phosphorous chloride, PCl_3, on orthophosphorous acid, when some phosphorus is formed at the same time. E. Giana said that phosphates are converted into pyrophosphates when heated to about 800° in a current of air and sulphur dioxide: $Ca_3(PO_4)_2+SO_2+O=CaSO_4+Ca_2P_2O_7$. Sodium pyrophosphate is formed when sodium hydrophosphate is heated: $2Na_2HPO_4=H_2O+Na_4P_2O_7$. When a soln. of normal sodium pyrophosphate is treated with lead nitrate or acetate, lead pyrophosphate, $Pb_2P_2O_7$, is precipitated. C. D. Braun obtained an aq. soln. of the acid from this salt. The lead salt was suspended in ice-cold water; decomposed by a stream of hydrogen sulphide; and the dissolved gas expelled by a current of air, and by agitation for some time with an excess of lead pyrophosphate. The clear soln. of pyrophosphoric acid cannot be well concentrated by evaporation because it is transformed into the ortho-acid during the operation. The liquid can be concentrated by fractional freezing. H. Giran[3] obtained solid pyrophosphoric acid by the action of dry hydrogen chloride on silver pyrophosphate, $Ag_4P_2O_7$, prepared in a similar manner to the corresponding lead salt.

The physical properties of pyrophosphoric acid.—As usually prepared, it is a syrupy liquid. T. Graham prepared pyrophosphoric acid as a soft glass by the evaporation of the aq. soln.; E. M. Péligot, and E. Zettnoff thought that they had obtained the acid in opaque crystals resembling glucose during the slow hydration of metaphosphoric acid. H. Giran found that syrupy pyrophosphoric acid yields white crystalline needles if it be kept about three months at —10°, but H. Giran believes that there is something wrong because the syrupy liquid is undercooled at ordinary temp. and crystallization occurs only when the liquid is seeded with other crystals of the acid, or by the prolonged action of cold. Even then the liquid is so viscid that crystallization occurs very slowly. According to H. Giran, these crystals have a **melting point** not lower than 61°, and a **heat of fusion,** —2·12 Cals. H. Giran found two minima on the f.p. curve of mixtures of water and pyrophosphoric acid—one at 23° with the eutectic $H_4P_2O_7+1{\cdot}25H_2O$, and the other at —75° with $H_4P_2O_7+6{\cdot}87H_2O$. The latter is probably the cryohydric temp. The maximum at 26° corresponds with **hydrated pyrophosphoric acid,** $H_4P_2O_7.1\frac{1}{2}H_2O$, which has been isolated in acicular crystals and which is less stable than that of the ortho-acid into which it readily passes. The dotted curve, Fig. 40, represents the f.p. curve of the binary system, pyrophosphoric acid and water. E. Cornec measured the **lowering of the freezing point** of pyrophosphoric acid by the progressive addition of potassium hydroxide, and the resulting curve showed singular points corresponding with the secondary, tertiary, and quaternary salts. The **index of refraction** of pyrophosphoric acid is 1·3435, and the value is lowered to a minimum, 1·3404, when 50 per cent. of potassium hydroxide has been added. Analogous results were obtained with aq. ammonia in place of potash-lye.

H. Giran's values, for the **heat of formation,** are $(2P,7O,4H)=H_4P_2O_{7\text{liq.}}+529{\cdot}94$ and 533·40 Cals.; $H_4P_2O_{7\text{solid}}$, 532·23 and 535·69; and $H_4P_2O_{7\text{soln.}}$, 540·16 and 543·62 Cals.; $H_4P_2O_{7\text{solid}}+1{\cdot}5H_2O_{\text{liq.}}=H_4P_2O_{7\text{solid}}+3{\cdot}44$ Cals.; and $H_4P_2O_{7\text{solid}}+1{\cdot}5H_2O_{\text{solid}}=H_4P_2O_{7\text{solid}}+1{\cdot}34$ Cals. H. Giran also gives for the **heat of solution,** $H_4P_2O_{7\text{solid}}+$aq. 7·78 and 7·93 Cals. $H_4P_2O_7.1\frac{1}{2}H_2O_{\text{solid}}+\text{aq.}=4{\cdot}49$ Cals., and $H_4P_2O_7.1\frac{1}{2}H_2O_{\text{liq.}}+\text{aq.}=7{\cdot}063$ Cals. H. Giran gives for the **heat of transformation** into orthophosphoric acid with liquid water: $H_4P_2O_{7\text{liq.}}+\text{aq.}=2H_3PO_{4\text{aq.}}+14{\cdot}47$ Cals.; $H_2P_2O_{7\text{liq.}}+H_2O$; $2H_3PO_{4\text{liq.}}+9{\cdot}09$ Cals.; $H_4P_2O_{7\text{solid}}+\text{aq.}=2H_2PO_{4\text{aq.}}+12{\cdot}35$ Cals.; $H_4P_2O_{7\text{solid}}+H_2O=2H_3PO_{4\text{solid}}+6{\cdot}97$ Cals.; $H_4P_2O_{7\text{aq.}}+H_2O=2H_3PO_{4\text{aq.}}+4{\cdot}25$ Cals. J. Thomsen gives for the **heat of neutralization,** $H_4P_2O_{7\text{aq.}}+nNaOH_{\text{aq.}}$, for $n=1$, 14·4 Cals.; for $n=2$, 28·6 Cals.; for $n=4$, 52·7 Cals.; and for $n=6$, 54·5 Cals. H. Giran also found for the first mol of sodium hydroxide, 15·29 Cals.; for the second, 15·65 Cals.; for the third, 13·11 Cals.; and for the fourth, 7·84 Cals.

For soln. containing C mols of the acid $H_4P_2O_7$ per litre, the mol. **electrical conductivity,** μ, found by G. A. Abbott and W. C. Bray, at 18°, is:

C . . .	0·05	0·025	0·0125	0·005	0·0025	0·00125
μ . . .	353·8	384·9	438·6	503·3	556·7	602·0

and for the primary, secondary, tertiary, and quaternary salts, they obtained :

	C	0·1	0·05	0·02	0·01	0·003	0·001	0·0003
μ	$NaH_3P_2O_7$	152·6	181·7	228·7	269·2	269·6	388·6	420·0

The results for the pyro-acid are so much like those for hypophosphoric acid, that E. Cornec argued a like complexity for the molecules of the two acids. G. A. Abbott and W. C. Bray calculated that with soln. containing c millimols of pyrophosphoric acid per litre, the **degree of ionization,** and the **ionization constants,** are :

c	50	25	12·5	5	2·5	1·25
Primary ionization	86	87	90	92	94	96 per cent.
$H_3P_2O'_7$-ions	34·3	15·6	6·73	2·02	0·75	0·27
$H_2P_2O_7$-ions	8·7	6·15	4·52	2·58	1·60	0·93
$H_4P_2O_7$-mols.	7·0	3·25	1·25	0·40	0·15	0·05
K_1	0·0132	0·0110	0·0106	0·0095	0·0084	0·0073
K_2	0·253	0·134	0·085	0·036	0·020	0·011

showing that the constants decrease with decreasing ionic conc. The ionization constant for $H_4P_2O_7=H_3P_2O'_7+H^\cdot$ is $K_1=0\cdot14$; for $H_3P_2O'_7=H_2P_2O''_7+H^\cdot$ is $K_2=0\cdot011$; for $H_2P_2O'_7=HP_2O'''_7+H^\cdot$ is $K_3=0\cdot0_629$; and for $HP_2O'''_7=P_2O''''_7+H^\cdot$ is $K_4=0_836$. I. M. Kolthoff obtained $K_3=3\cdot6\times10^{-9}$ to $4\cdot6\times10^{-9}$; and $K_4=7\cdot6\times10^{-7}$. W. Hittorf found the **transport number** of normal sodium pyrophosphate in aq. soln. to be 0·645.

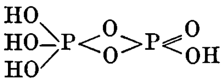
The hydration of pyrophosphoric acid.—T. Graham kept an aq. soln. of dil. pyrophosphoric acid for six months without change ; but, when heated, it was converted into the ortho-acid. The hydration of dil. soln. of pyrophosphoric acid is therefore slow at ordinary temp., but it is rapid when boiled. M. Berthelot and G. André [4] found that a soln. of pyrophosphoric acid contained after standing :

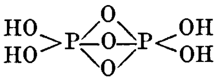
	5	10	19	52	89	110	121 days
$H_4P_2O_7$	87	83	76·5	69·5	58	49·5	43·1
H_3PO_4	4	8	14·5	21·5	33	41·5	47·9

There was no sign of the formation of any metaphosphoric acid ; the more conc. the soln. the faster the change, or the more dil. the soln. the greater the stability. P. Sabatier found that the presence of a strong acid—sulphuric or hydrochloric acid—accelerates the hydration, while a weak acid—*e.g.* acetic acid—retards the conversion. C. Montemartini and U. Egidi found the reaction is of the first order : $H_4P_2O_7+aq.=2H_3PO_{4aq.}$. The speed of hydration is faster than with metaphosphoric acid. The speed of hydration has also been measured by G. A. Abbott, who found that the rate is nearly ten times faster at 100° than it is at 75°. L. Pessel found that the rate of hydration is accelerated by $H^\cdot$-ions ; and that mixtures with hydrochloric have a low electrical conductivity owing to the feeble ionization of a compound of the two acids.

The constitution of pyrophosphoric acid.—The analyses of T. Graham,[5] and E. M. Péligot established the empirical composition of pyrophosphoric acid, $H_4P_2O_7$. H. Giran found that the mol. wt. of a soln. of pyrophosphoric acid in glacial acetic acid decreases with time, and this the more the less the conc. of the soln. By extrapolation for zero time, he obtained the mol. wt. 534 corresponding with $(H_4P_2O_7)_3$. According to A. Holt and J. E. Myers, also, the f.p. of aq. soln. of the viscid, syrupy liquid, obtained by dehydrating the ortho-acid, is depressed in agreement with the assumption that the molecules of the acid are complex—between $(H_4P_2O_7)_4$ and $(H_4P_2O_7)_5$; while the soln. derived from the decomposition of the lead-salt contain the simple molecules $H_4P_2O_7$. The f.p. of freshly prepared soln. in acetic acid correspond with the mol. wt. $(H_4P_2O_7)_3$; and as time goes on, the mol. wt. diminishes to something between $(H_4P_2O_7)_2$ and $H_4P_2O_7$, which makes it appear as if in acetic acid soln., pyrophosphoric acid gradually depolymerizes. Strictly speaking, *orthodiphosphoric acid* should be $(HO)_4P.O.P(OH)_4$, represented by lead orthodiphosphate (*q.v.*), so that the ordinary acid is derived from this by the loss of 2 mols of water, furnishing probably $(HO)_2PO.O.PO(OH)_2$, which, in harmony with the nomenclature employed for the silicic acids—**6**. 40, 22—becomes *deuterodiphosphoric acid;* but this is commonly regarded as the ortho-acid. D. Balareff said that the molecule is probably not associated.

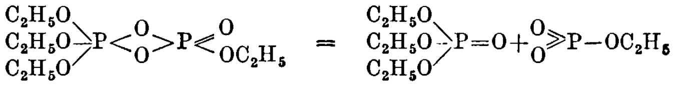
The heats of neutralization of pyrophosphoric acid with sodium hydroxide show that the acid is probably tetrabasic, for H. Giran found that the first two displaceable hydrogen atoms have strongly marked acidic functions, and the other two have feeble acidic functions. The graphic formula $(HO)_2{=}PO.O.PO{=}(OH)_2$ is in agreement with the tetrabasicity of the acid, and with the work of W. A. Tilden and R. E. Barnett. C. Favel also found pyrophosphoric acid behaved like a tetrabasic acid towards "soluble blue" indicator. The confident assumption that the phosphorus is quinquevalent precludes H. Wichelhaus' formula $(HO)_2P.O.O.O.P(OH)_2$; but, before the formula $(HO)_2PO.O.PO(OH)_2$ can be definitely accepted, it must be shown that the formulæ





are inadequate. The work of G. A. Abbott and W. C. Bray on the step-by-step ionization of the four hydrogen atoms of pyrophosphoric acid, indicated above, shows that the first two constants have nearly the same value, and are very different from the last pair of constants which are not very different from one another. This has been taken to mean that the four hydroxyl groups in the molecule of pyrophosphoric acid are related to one another in pairs, and that the formula of the acid is symmetrical, $(HO)_2PO.O.PO(OH)_2$ or $(HO)_2$ or $(HO)_2P{<}O_3{>}P(OH)_2$, and not asymmetrical, $(HO)_3P{<}O_2{>}PO.OH$. A. Geuther and A. Michaelis argued that since pyrophosphoryl chloride, $P_2O_3Cl_4$, yields orthophosphoric acid, not pyrophosphoric acid, when treated with water, the acid has probably the unsymmetrical formula $(HO)_3P{<}O_2{>}PO(OH)$. However, this argument loses its force when it is remembered that the heat of the reaction is so great that even if the pyro-acid were formed, it would be converted into the ortho-acid, owing to the consequent rise of temp. When the conditions of the reaction are such that it takes place slowly and less vigorously—say, by the action of moist air on pyrophosphoryl chloride, or of water on a dil. soln. of the chloride in carbon disulphide—pyrophosphoric acid is formed along with a little of the ortho-acid. Consequently, the formula of pyrophosphoric acid most probably depends on what formula best represents the constitution of pyrophosphoryl chloride (*q.v.*). D. Balareff said that the character of the ionization constants; the conditions of dehydration; the reaction with phosphorus pentachloride and sodium pyrophosphate in a sealed tube over 300°: $Na_4P_2O_7+3PCl_5=NaPO_3+3NaCl+4POCl_3$; the decomposition of $NaAg_3P_2O_7$ on fusion yielding Ag_3PO_4 and $NaPO_3$; and the formation of pyrophosphoric acid and metaphosphoric acid by the action of thionyl chloride on orthophosphoric acid, and the formation of pyrophosphoric acid alone when sulphuryl chloride is used, all favour the unsymmetrical formula.

Pyrophosphoric acid behaves like a monobasic acid when titrated with sodium hydroxide if cochineal be the indicator; and as a dibasic acid if Porrier's blue be the indicator. The tetrabasicity of pyrophosphoric acid is confirmed by the establishment of the molecular formula $(C_2H_5)_4P_2O_7$ for ethyl pyrophosphate, by J. Cavalier, by measuring its effect on the b.p. of benzene. When ethyl pyrophosphate is distilled, it breaks down into ethyl orthophosphate, $(C_2H_5)_3PO_4$, and probably ethyl metaphosphate, $C_2H_5PO_3$, which immediately decomposes into ethylene, C_2H_4, and metaphosphoric acid: $C_2H_5PO_3=C_2H_4+HPO_3$—the triethyl orthophosphate distils unchanged. The asymmetrical formula for pyrophosphoric acid explains this reaction very well:



$$\begin{matrix}C_2H_5O\\C_2H_5O\\C_2H_5O\end{matrix}{>}P{<}\begin{matrix}O\\O\end{matrix}{>}P{<}\begin{matrix}O\\OC_2H_5\end{matrix} = \begin{matrix}C_2H_5O\\C_2H_5O\\C_2H_5O\end{matrix}{>}P{=}O+\begin{matrix}O\\O\end{matrix}{\gg}P-OC_2H_5$$

Similarly, A. Rosenheim and M. Pritze found that the raising of the b.p. of methyl or ethyl iodide by methyl pyrophosphate agrees with the mol. wt. of the methyl ester—between 239 and 264·5—and corresponds with the value 243 calculated for $(CH_3)_4P_2O_7$. Similarly for ethyl pyrophosphate.

The pyrophosphates.—The pyrophosphates are prepared by mixing aq. soln. of the acid and base; by calcining a mol. of ortho- and meta-phosphoric acids with two mols. of a uniacid base, or the eq. of a polyacid base; and by heating, say, disodium hydrogen phosphate to 240°, or di-silver hydrogen phosphate to 170°, etc. J. H. Gladstone[6] found that many insoluble pyrophosphates are precipitated on metals, some of the precipitates form soluble double salts when treated with an excess of the soln. of sodium pyrophosphate—*e.g.* iron, copper, mercurous, zinc, cobalt, nickel, manganese, uranium, and aluminium pyrophosphates —but not mercuric or chromic salts; the addition of sulphuric acid to the soln. of the double salt may give a precipitate which re-dissolves in the dil. acid soln.; and treatment of the soln. of the double pyrophosphate with ammonium sulphide precipitates the sulphides of zinc, cobalt, nickel, and iron, but not manganese, uranium, chromium, or aluminium.

Curiously enough, tetrabasic pyrophosphoric acid readily forms *quaternary* or normal pyrophosphates, say $Na_4P_2O_7$, etc.; and the *secondary* pyrophosphates, say $Na_2H_2P_2O_7$, but not the primary and tertiary salts. There is even some doubt if the ternary salt, $Na_3HP_2O_7$, and the primary salt, $NaH_3P_2O_7$, have been prepared. T. Salzer reported the former in 1894; and H. Giran, the latter in 1903. Abortive attempts have been made to prepare a pair of isomeric potassium sodium pyrophosphates:

$$\begin{matrix}KO\\NaO\end{matrix}{>}PO.O.PO{<}\begin{matrix}OK\\ONa\end{matrix}$$

Symmetrical.

$$\begin{matrix}KO\\KO\end{matrix}{>}PO.O.PO{<}\begin{matrix}ONa\\ONa\end{matrix}$$

Asymmetrical.

the first by calcining potassium sodium orthophosphate, and the second by calcining a mixture of dipotassium and disodium orthophosphates:

$$\begin{matrix}KO\\NaO\end{matrix}{>}PO-\boxed{OH\ H}O-PO{<}\begin{matrix}OK\\ONa\end{matrix}$$

$$\begin{matrix}KO\\KO\end{matrix}{>}PO-\boxed{OH\ H}O-PO{<}\begin{matrix}ONa\\ONa\end{matrix}$$

Pyrophosphoric acid, said A. B. Poggiale, is not poisonous in dil. soln. and M. Paquelin and L. Jolly said that the pyrophosphates pass through the system unchanged but act as diuretics. The quaternary salts, $M_4P_2O_7$, are not changed by heat unless they are salts of the metals whose oxides are readily decomposed by heating; the secondary salts, $M_2H_2P_2O_7$, form metaphosphates and water; all the pyrophosphates are converted into orthophosphates when heated with alkali hydroxides or carbonates: $M_4P_2O_7+M_2O \rightarrow 2M_3PO_4$. H. Struve found that the pyrophosphates of the metals whose oxides are reduced when heated with **hydrogen** are decomposed when heated with this gas, forming the metal phosphide, orthophosphoric acid, and water; pyrophosphates of the metals whose oxides are not reduced when heated with hydrogen form orthophosphates, phosphorous oxide, and sometimes also phosphine, and a little red phosphorus; the pyrophosphates of the metals whose oxides are reduced by heat alone form orthophosphates, the metal, water, etc., when heated with hydrogen. H. Rose says that aq. soln. of the alkali pyrophosphates are not changed either by standing for a long time, or by boiling with **water**; J. H. Gladstone also said that the quaternary pyrophosphates are not changed by boiling with water or neutral salt soln.; but A. Reynoso found that by heating them with water to 280°, they are changed into secondary orthophosphates if they give an insoluble orthophosphate; and into a primary orthophosphate—*vide supra* for the hydration of pyrophosphoric acid. The secondary salts react feebly acidic with both litmus and phenolphthalein, but neutral with methyl-orange. The normal or quaternary alkali pyrophosphates are soluble in water, and the aq. soln. has a feeble alkaline reaction. T. Salzer said that the **halogens** react with an aq. soln. of sodium pyrophosphate, forming sodium bromide, hypobromite, and hydropyrophosphate, leaving much pyrophosphate unattacked. When boiled with **acids,** say sulphuric acid, R. Weber found that the pyrophosphates are transformed into the ortho-salts, but the pyrophosphates were found by E. F. Smith and J. G. Gibbs not to be attacked by **hydrogen chloride.** According to H. Rose, the pyrophosphates are transformed into orthophosphates by fusion with **alkali carbonates.** H. Girard formed orthophosphoric acid and sodium thiosulphate with the evolution of hydrogen sulphide by boiling aq. soln. of sodium pyrophosphate with flowers of **sulphur.** T. Salzer stated that no orthophosphoric acid is formed, but the reaction occurs in the sense of the equation: $x\mathrm{Na_4P_2O_7}+12\mathrm{S}+3\mathrm{H_2O}=2\mathrm{Na_2S_5}+\mathrm{Na_2S_2O_3}+6\mathrm{Na_3HP_2O_7}+(x-6)\mathrm{Na_4P_2O_7}$, where x depends on the conc., temp., and press. G. Buchner found that **ammonium sulphide** precipitates zinc, cobalt, nickel, and iron, but not manganese, uranium, or chromium from soln. of the double pyrophosphates. The action of the **phosphorus chlorides** is not to chlorinate pyrophosphoric acid to pyrophosphoryl chloride, $\mathrm{P_2O_3Cl_4}$—as might be expected: $\mathrm{H_4P_2O_7}+\mathrm{PCl_5}=\mathrm{H_3PO_4}+\mathrm{P_2O_3Cl_4}+\mathrm{HCl}$—but rather to dehydrate the pyro- to the meta-acid, thus, when pyrophosphoric acid is heated with **phosphorus pentachloride,** $\mathrm{PCl_5}$, A. Geuther showed that it forms phosphoryl chloride: $\mathrm{H_4P_2O_7}+\mathrm{PCl_5}=2\mathrm{HPO_3}+\mathrm{POCl_3}+2\mathrm{HCl}$, or in the extreme case: $\mathrm{H_4P_2O_7}+5\mathrm{PCl_5}\rightarrow 4\mathrm{HCl}+7\mathrm{POCl_3}$—it may be that pyrophosphoryl chloride is first formed, and subsequently breaks down to phosphoryl chloride by a secondary reaction: $2\mathrm{P_2O_3Cl_4}+2\mathrm{PCl_5}\rightarrow 6\mathrm{POCl_3}$; pyrophosphoric acid also reacts slowly with **phosphoryl chloride**: $2\mathrm{H_4P_2O_7}+\mathrm{POCl_3}=5\mathrm{HPO_3}+3\mathrm{HCl}$; and with **phosphorus trichloride,** $\mathrm{PCl_3}$, it forms metaphosphoric and phosphorous acids: $\mathrm{PCl_3}+3\mathrm{H_4P_2O_7}=6\mathrm{HPO_3}+\mathrm{H_3PO_3}+3\mathrm{HCl}$; similar remarks apply to the action of **thionyl chloride,** $\mathrm{H_4P_2O_7}+\mathrm{SOCl_2}\rightarrow 2\mathrm{HPO_3}+\mathrm{SO_2}+2\mathrm{HCl}$. P. de Clermont prepared **tetraethyl pyrophosphate,** $\mathrm{(C_2H_5)_4P_2O_7}$, by the action of ethyl iodide, $\mathrm{C_2H_5I}$, on silver pyrophosphate, $\mathrm{Ag_4P_2O_7}$, at 100°. The liquid has a sp. gr. 1·17 at 17°; it is soluble in water and alcohol; it decomposes when heated; and it forms with potash-lye, **diethyl potassium orthophosphate,** $\mathrm{K(C_2H_5)_2PO_4}$. W. W. Worms, and A. A. Panormoff studied the soluble compounds pyrophosphoric acid forms with **albumen.** The aq. soln. of the pyrophosphates give a white precipitate with soln. of **silver nitrate,** and with **barium or calcium chloride.** According to J. L. Lassaigne, these reactions are so sensitive that a strong turbidity is produced with soln. containing one part of the acid in 10,000 parts of water; a faint turbidity with 1 : 20,000; and very faint with 1 : 40,000—that with the calcium salt appears only in about half an hour; with 1 : 80,000, the calcium salt gives no turbidity, the other salts give a faint cloudiness; and with 1 : 160,000, a faint opalescence. W. Gibbs observed that pyrophosphoric acid forms complexes with **tungstic acid.**

§ 26. Metaphosphoric Acid

J. J. Berzelius[1] showed that when ordinary phosphoric acid is calcined, the product is fundamentally different from orthophosphoric acid in that it has acquired the power of coagulating a soln. of albumen. The same product is obtained by the action of a small proportion of water on phosphorus pentoxide; and H. Giran said that the main product of the first action is metaphosphoric acid. E. B. R. Prideaux noted that 75 per cent. of metaphosphoric acid is formed during the dissolution of phosphoric pentoxide in an excess of water at room temp.—the remainder is orthophosphoric acid. T. Graham further showed that by gradually heating sodium dihydrogen or diammonium phosphate, three different salts can be obtained, and he investigated the properties of the product which appears as a vitreous or glassy mass and which, for a time, was named *Graham's salt;* it has the empirical composition $NaPO_3$, sodium monometaphosphate: $Na(NH_4)_2PO_4=H_2O+2NH_3+NaPO_3$. T. Graham says that the syrupy acid is preferably heated in a gold crucible since other metals, including platinum, are attacked. The aq. soln. of the cold mass when treated with lead nitrate furnishes a precipitate of the lead salt, $Pb(PO_3)_2$; when the washed precipitate, suspended in water, is treated with hydrogen sulphide, lead sulphide is precipitated. The excess of hydrogen sulphide is driven from the aq. soln. by a current of air, and a soln. of metaphosphoric acid remains. W. Gregory, R. Maddrell, A. Joly, etc., prepared the acid by calcining orthophosphoric acid to 316°, and they considered pyrophosphoric acid to be an intermediate product of the transformation. A. Joly

also prepared the meta-acid by the action of heat on pyrophosphoric acid; G. Watson says the conversion occurs between 290° and 300°; and G. Tammann, that the transformation occurs when the ortho-acid is heated beyond the point where it begins to fume. A. Besson obtained metaphosphoric acid by heating ammonium hydrophosphate, $(NH_4)_2HPO_4$. Metaphosphoric acid was prepared by A. Besson, by the action of hydriodic acid on phosphoryl chloride; G. Gustavson, by heating iodine or bromine with orthophosphorous acid, H_3PO_3, in a sealed tube at 100°: $2H_3PO_3+2Br_2=4HBr+2HPO_3$; if a smaller proportion of bromine be used, the ortho-acid is formed: $4H_3PO_3+3Br_2=3HBr+PBr_3+3H_3PO_4$. O. Ordinaire, however, obtained monobromophosphorous acid by heating two gram-molecules of bromine with one of phosphorous acid. A. Geuther obtained metaphosphoric acid by the action of an excess of phosphoryl chloride on orthophosphoric acid: $3H_3PO_4+PCl_3=3HPO_3+H_3PO_3+3HCl$; phosphorous chloride gave a similar result: $2H_3PO_4+POCl_3=3HPO_3+3HCl$. C. F. Gerhardt found the meta-acid to be produced by heating moist phosphamide or phospham in the absence of air: $HPN_2+3H_2O=2NH_3+HPO_3$. H. Schiff also found it to be produced when phosphoryl chloride acts upon salicylic or other polybasic acids.

Some physical properties of metaphosphoric acid.—Metaphosphoric acid is a transparent, vitreous solid sometimes called *glacial phosphoric acid.* E. Brescius[2] said that the glacial acid is soft and flexible, and the presence of sodium phosphate makes it hard. The commercial acid is sold in sticks, and, according to A. Bettendorff, it often contains some sodium salts and some ortho- and pyro-acids as impurities. The dry acid deliquesces rapidly in air, and it readily dissolves in water with the development of much heat. The acid solidifies to a vitreous mass without crystallization from solutions with less than 63 per cent. of water. P. Harting says that one part of the acid in 10,000 parts of water reddens blue litmus. According to H. Rose, metaphosphoric acid volatilizes at a bright red-heat, and is not dehydrated further than $(HPO_3)_n$ by heat or by dehydrating agents, although W. A. Tilden and R. E. Barnett find that at a high temperature there are signs of the loss of a little water because the product contained rather more phosphoric anhydride than corresponds with the formula HPO_3. H. Giran did not succeed in obtaining a f.p. curve of mixtures of the meta-acid and water because of the formation of vitreous glasses. F. M. Raoult, and E. Cornec measured the **lowering of the freezing point** of aq. soln. of metaphosphoric acid and obtained results in agreement with a polymerized molecule. According to H. Giran, the **heat of formation** is $(H,P,3O)=HPO_{3\text{solid}}+$between 224·88 and 226·61 Cals. and $(H,P,3O)=HPO_{3\text{aq.}}+236{\cdot}37$ Cals. H. Giran gives for the **heat of solution** of the solid acid 9·76 Cals., while A. Joly gives 4·63 Cals. The **heat of neutralization** of a mol. of potassium hydroxide, by water sat. with metaphosphoric acid, is 325·4 units; similarly, for sodium hydroxide, 474·4 units. J. Thomsen obtained: $2HPO_{3\text{aq.}}+NaOH_{\text{aq.}}=14{\cdot}4$ Cals.; and $2HPO_{3\text{aq.}}+2NaOH_{\text{aq.}}=28{\cdot}75$ Cals. H. Giran found $NaOH_{\text{aq.}}+HPO_{3\text{aq.}}=14{\cdot}84$ Cals., and $NaOH_{\text{solid}}+HPO_{3\text{solid}}=63{\cdot}03$ Cals.; he also gives 10·22 Cals. for the **heat of transformation** of HPO_3 with H_3PO_4. J. H. Gladstone gives 18·68 for the **refraction equivalent,** and, for the **index of refraction** of a soln. in 8·23 eq. of water (sp. gr. 1·270) at 20·5°, 1·3718 for the *A*-linc, 1·3764 for the *D*-line, and 1·3879 for the *H*-line. F. Zecchini has studied the molecular refraction of the metaphosphates; and A. Kundt, the double refraction—C. Zakrewsky and G. Kraft found that the optical behaviour of the acid is like that of an oil. W. W. Coblentz found metaphosphoric acid to be too opaque to give other than an imperfect **ultra-red transmission spectrum.**

G. Janecek[3] observed that spontaneously inflammable phosphine is evolved during the electrolysis of solutions of the metaphosphates. S. Arrhenius, in his thesis *Recherches sur le conductibilité galvanique des electrolytes* (Stockholm, 1884), gave measurements of the electrical resistance, and the **electrical conductivity** of the acid. E. B. R. Prideaux found the meta-acid has a greater conductivity than the ortho-acid; while A. Holt and J. E. Myers found the meta-acid to be slightly ionized in aq. soln. Starting with an acid containing about 75 per cent. of metaphosphoric acid and 25 per cent. of orthophosphoric acid, E. B. R. Prideaux found that the electrical conductivity for the first 20 hrs. suffers but little change; it then decreases in accord with an exponential law for about 160 hrs., and thereafter decreases at a rather slower rate as illustrated by Fig. 48. The alteration is attended by a change from polymerized $(HPO_3)_n$ to simple HPO_3 mols, the former being a bad conductor; the polymerization of the $(HPO_3)_n$-acid attended by a hydration of the HPO_3-acid to H_3PO_4, the former change being probably the quicker. Fig. 47 shows the sp. conductivity of the acid for different conc. at 18° and at 25° of the mixed acids. The actual conductivity of the simple metaphosphoric acid alone is unknown, since the aq. soln. always contains the polymerized acid and orthophosphoric acid as well. When the hydration is complete, the conductivities of the soln. correspond with those required for orthophosphoric acid. Starting from the right, the curves, Fig. 48, show that the conductivity increases only slightly with the change in the conc. of the soln. This is presumably due to the presence of the polymerized, non-conducting molecules. It is then inferred that the lower part of the curves represents the relation between conductivities and conc. of simple molecules HPO_3 and H_3PO_4. If the curve is continued on this assumption, the point where it strikes the ordinate from 240 millimols per litre represents the theoretical conductivity of HPO_3. The conductivity so found is 544 at 18° and 590 at 25°, the percentage increase for 1° being 1·2, as in soln. of partly changed HPO_3. If this represents the conductivity of non-polymerized HPO_3, it is interesting to notice that it is of the same order as that of iodic acid at 250 millimols per litre, namely, 573. W. Hittorf found the transport number of the anion of normal sodium metaphosphate to be 0·573; and A. Wicsler, 0·590.

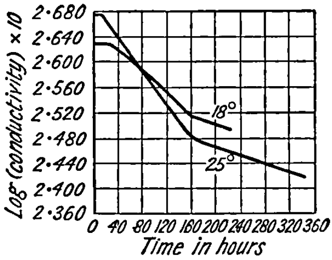

FIG. 47.—The Change of the Electrical Conductivity of Metaphosphoric Acid Solutions with Time.

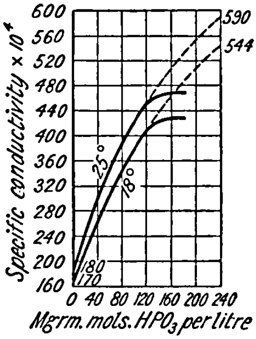

FIG. 48.—The Electrical Conductivity of Solutions of Metaphosphoric Acid.

The hydration of metaphosphoric acid.—The aq. soln. of metaphosphoric acid was found by T. Graham[4] to pass slowly into the ortho-acid, but not into the pyro-acid; the change is accelerated by boiling the soln., or by treating it with acids. According to A. Vogel, the change of meta- to the ortho-acid, in aq. soln., is not accompanied by any change in vol.; and C. Montemartini and U. Egidi found the reaction is unimolecular: $HPO_3+H_2O=H_3PO_4$. The velocity of transformation is faster the greater the concentration of the metaphosphoric acid in soln. J. C. and F. C. Blake did not find the reaction to be proportional to the amount of unchanged substance left in the soln., and H. Giran found the speed of hydration of metaphosphoric acid to be faster than that of the pyro-acid, and that the reaction is too complex to be represented by a simple equation. This latter result was also obtained by A. Holt and J. E. Myers. The speed of the reaction is very sensitive to variations of temp. Thus, P. Sabatier found that a

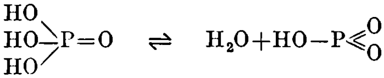
$\frac{1}{2}N$-soln. required 150 days for complete conversion to the ortho-acid at 0°, it required but 5 days at 31°, and less than an hour at 95°. P. Sabatier also found that the presence of a strong mineral acid, like sulphuric or hydrochloric acid, accelerates the change, while a weak organic acid, like acetic acid, retards the conversion; he further proved that the transformation is arrested if the metaphosphoric acid be completely neutralized by a strong base like sodium hydroxide, for, at 0° no change was observed, and only a slight formation of the ortho-salt at 43·5°. With the protracted boiling of the soln. the meta-salt was completely transformed into the ortho-salt; if the meta-acid be incompletely neutralized the transformation is slower than with the free acid, and faster than with the completely neutralized acid; while if some alkali be in excess, the transformation is rather slower than with the completely neutralized acid.

There have been some differences of opinion as to whether the meta-acid is hydrated directly into the ortho-acid, or whether it passes *viâ* the pyro-acid as an intermediate stage. T. Graham, J. M. Maisch, P. Sabatier, C. Montemartini and U. Egidi, and D. Balareff supposed the change to be direct; while M. Berthelot and G. André, S. Tanatar, and H. Giran considered the pyro-acid to be formed as an intermediate product. It is known that the dehydration of the ortho-acid produces first the pyro-acid and then the meta-acid; and it might be expected that the rehydration of the meta-acid would take place in the reverse manner. The trouble has arisen from the difficulties in detecting the pyro-acid in the presence of the meta- and ortho-acids; and, on account of the polymerization of the different acids in aq. soln., physical methods of testing the hypothesis give ambiguous results. A. Holt and J. E. Myers were able to demonstrate the intermediate formation of the pyro-acid in the hydration of the meta- and the ortho-acid by the fractional precipitation of the soln. by adding silver nitrate in small portions at a time, and filtering off the resulting precipitates one by one. At first yellow silver ortho-phosphate separates, and afterwards a colourless precipitate is obtained—the absence of colour shows that the precipitate is either silver pyro- or meta-phosphate. When the precipitate is washed and treated with hydrochloric acid to precipitate the silver, a soln. is obtained which does not coagulate albumen, showing the absence of metaphosphoric acid. The accumulation of the pyro-acid in the soln. shows that the passage from the meta- to the pyro-acid is faster than the change from the pyro- to the ortho-acid. Again, the transformation of meta- to ortho-phosphoric acid is faster the more conc. the soln., and the higher the temp.—*e.g.* the transformation of a $\frac{1}{2}N$-soln. at 0° occupies about 150 days; at 31°, about 5 days; and at 95°, less than half an hour. The presence of strong mineral acids—sulphuric or hydrochloric acid—accelerates the change; while the weak acids—acetic acid—retards the speed of conversion; the presence of alkalies also retards the change. L. Pessel found that $H^{\cdot}$-ions accelerate the rate of hydration; that the velocity constant increased with time owing to the polymerization of the metaphosphoric acid; that pyrophosphoric acid is not formed as an intermediate compound in the process; and, as pointed out by P. Sabatier, the conversion of sodium metaphosphate to orthophosphate is accelerated by an excess of alkali.

Four varieties of metaphosphoric acid have been reported. (i) The meta-acid, prepared by heating commercially pure glacial phosphoric acid for a short time to redness, furnishes a glassy solid which is deliquescent in moist air, and quickly dissolves in water to form a soln. whose f.p. corresponds with the presence of molecules, $(HPO_3)_3$; T. Graham's soluble salt, sodium metaphosphate, in aq. soln. also has a mol. wt. corresponding with $(NaPO_3)_3$. (ii) If the preceding variety of the meta-acid be heated for several hours to redness, it forms a brittle glass with a sp. gr. 2·488. This is less deliquescent in moist air than the former modification, and, when placed in water, it appears to decrepitate, minute particles being shot into the liquid so as to form a turbid soln. (iii) When this crackling variety is heated for about 24 hrs. at a dull red-heat, it forms a brittle glass with a sp. gr.

2·216; this form of the acid does not deliquesce, unless perhaps very slowly, and it dissolves very slowly in water. The dissolution in water is not attended by any crackling phenomenon as is the case with the preceding variety. F.p. determinations indicate that the soln. contains molecules of $(HPO_3)_2$. (iv) According to A. Holt and J. E. Myers, aq. soln. of the acid prepared by decomposing lead metaphosphate have a f.p. in agreement with a soln. of mol. wt. HPO_3. E. Cornec has shown that the mol. wt. of metaphosphoric acid in water, and others, in acetic acid soln., varies with time presumably because the acid becomes complex.

Analyses of metaphosphoric acid, by E. M. Péligot, R. Weber, P. L. Dulong, H. Rose, and W. A. Tilden and R. E. Barnett, agree with the empirical formula HPO_3. That by C. L. Berthollet is more like pyrophosphoric acid. W. A. Tilden and R. E. Barnett showed that the mol. wt. of metaphosphoric acid when in a state of vapour at a bright red-heat is 76·8, and 78·2 when the theoretical value for $(HPO_3)_2$ is 80—hence the vapour is a bimolecular complex, $(HPO_3)_2$, which shows signs of dissociation at elevated temp., and parts with a little water. Hence, the meta-acid may be related to the pyro-acid as $HO{-}PO{=}O_2{=}PO{-}OH$ and $(HO)_2{=}PO{-}O{-}PO{=}(OH)_2$. The ordinary method of representing the dehydration of the ortho-acid is:



$$\begin{matrix}\mathrm{HO}\\ \mathrm{HO}\\ \mathrm{HO}\end{matrix}{>}\mathrm{P{=}O} \rightleftharpoons \mathrm{H_2O+HO{-}P}{\lessgtr}^{\mathrm{O}}_{\mathrm{O}}$$

which favours the idea that metaphosphoric acid bears the same relation to phosphorus that nitric acid bears to nitrogen. H. Giran found the mol. wt. in glacial acetic acid soln. decreases with time, and approximates to a limiting value 400 for zero time—this agrees with the formula $(HPO_3)_5$—and the limiting value is smaller the more dil. the soln. E. B. R. Prideaux also found the soln. to contain simple and polymerized molecules. According to A. Hantzsch, metaphosphoric acid in conc. sulphuric acid soln. behaves as if it were split into two ions.

The chemical properties of metaphosphoric acid.—A. B. Poggiale[5] said that the dil. aq. soln. of the acid is not poisonous, and that the conc. soln. acts like other strong acids. O. Schulz found that subcutaneous injections in rabbits had a toxic action. J. J. Berzelius found that metaphosphoric acid deliquesces rapidly when exposed to **air**; and dissolves in **water** with the development of much heat. When water is poured over the glacial acid, the mass splits with violence into small pieces, some of which are projected upwards. Dissolution occurs only slowly. The action of water has been already discussed. Owing to the probable fact that solid metaphosphoric acid is polymerized and that when dissolved in water depolymerization and hydration simultaneously occur, the reported properties—physical and chemical—of this acid are affected accordingly. P. Harting said that one part of the acid in 10,000 parts of water will redden blue litmus. H. Giran attempted to determine the solubility curve of metaphosphoric acid in water as he did for the ortho- and pyro-acids, but he found that the soln. of the meta-acid froze to vitreous glasses, and did not crystallize. D. Balareff observed that an aq. soln. of metaphosphoric acid slowly forms orthophosphoric acid on keeping. According to T. Fleitmann, and G. von Knorre, the *monometaphosphates* are usually very sparingly soluble in water, so that, as T. Graham noted, **potassium hydroxide** precipitates from the aq. soln. Not one of the three acids—ortho-, pyro-, or meta- —is changed by hydrogen, although W. A. Ross found that when metaphosphoric acid is heated with **zinc**, phosphine is formed; when heated with **aluminium,** L. Frank found that an aluminate, aluminium phosphide, and phosphorus are formed; when the acid is heated with **carbon,** W. Neumann noted that phosphorus is set free; when heated with **silica,** P. Hautefeuille and J. Margottet, and K. Hüttner obtained the complex $P_2O_5.SiO_2$. W. Gibbs also obtained complexes with **molybdic acid** and with **tungstic acid**. A. Geuther found that when warmed with **phosphorus pentachloride,** metaphosphoric acid reacts $HPO_3+2PCl_5=3POCl_3+HCl$; while **phosphoryl chloride** and **phosphorus trichloride** have no action. C. F. Schönbein found when melted with **iodides,** the reaction is violent, iodine and hydrogen iodide being given off. J. Heimann found that metaphosphoric acid does not dissolve in hydrocarbons; it dissolves in all proportions in **acetic anhydride,** in **benzaldehyde, benzophenone,** and other organic **anhydrides, aldehydes,** and **ketones.** He also found that **zinc, lead, tin, iron, copper,** and **silver** are dissolved by soln. of metaphosphoric acid, while **platinum** is not attacked. The electrochemical series is in the order named. W. Schlömann found that a freshly prepared conc. soln. gives a precipitate with an alcoholic or ethereal soln. of the **primary mono-** or **di-amines,** but not with the **secondary** or **tertiary amines.** R. Lorenz found that metaphosphoric acid forms a compound with **gluten.**

Aq. soln. of the pyrophosphates give a white crystalline precipitate with **silver nitrate**—orthophosphates give a yellow precipitate, and metaphosphates give a white gelatinous precipitate—all three precipitates are soluble in ammonia, and in nitric acid, so that the precipitate is formed only in neutral soln. The pyrophosphates give a white earthy precipitate with **barium or calcium chloride or nitrate** provided the soln. is not acidic—similar results are obtained with the ortho- and the meta-phosphates. All three precipitates are soluble in acids—even acetic acid—and hence differ from ferric and aluminium phosphates. Ammonia re-precipitates the phosphate from the soln. in acids. These salts have been also studied by C. Hindenlang, G. Denigés, and F. Warschauer. According to P. Harting, precipitates can be obtained with calcium or lead salts from soln. of one part of pyrophosphoric acid in 10,000 parts of water, or in 20,000 parts of water if the mixture is allowed to stand for half an hour. **Magnesium chloride** gives a white precipitate with pyrophosphates—the precipitate is soluble in an excess of the pyrophosphate or magnesium salt; moderately dil. soln. of the metaphosphates give no such precipitate, and orthophosphates give a precipitate in the presence of ammonium chloride and ammonia. A soln. of **albumen** and acetic acid gives no precipitate with pyrophosphates—alkalies should be absent since alkali acetates give precipitates even in the absence of albumen. The alkali metaphosphates do not coagulate albumen, but free metaphosphoric does do so. **Ammonium molybdate** gives no precipitate in the cold with nitric acid soln. of meta- and pyro-phosphates, but the ortho-phosphates give a yellow crystalline precipitate of ammonium phosphomolybdate: $H_3PO_4+12(NH_4)_2MoO_4+21HNO_3=(NH_4)_3PO_4.12MoO_3+21NH_4NO_3+12H_2O$; the yellow precipitate is readily soluble in ammonia, alkali-lees, and in an excess of a soln. of alkali phosphate; and compounds are formed containing less molybdenum than is represented by this equation. Hence, in the gravimetric determination of phosphates by this reaction, it is necessary to employ a large excess of the ammonium molybdate soln. to prevent the formation of a precipitate low in molybdenum. If the meta- or pyro-phosphates are boiled with the ammonium molybdate, the yellow precipitate is formed because the meta- and pyro-phosphates are changed into the ortho-salt. According to C. D. Braun,[6] luteocobalt chloride, or **cobaltic sodium hexamminopyrophosphate,** when added drop by drop to a soln. of an alkali pyrophosphate (neutralized with an alkali), forms a reddish-yellow crystalline precipitate resembling lead iodide, and which, according to S. M. Jörgensen, has the composition, $[Co(NH_3)_6]NaP_2O_7.11\frac{1}{2}H_2O$. If metaphosphates be present, some may be carried down mechanically with the precipitated pyrophosphate, otherwise the reaction could be applied quantitatively. Alkali salts of the ortho- and metaphosphates do not give precipitates with the luteocobalt chloride unless the mixture has stood for some hours, and even then the precipitates are readily distinguished from that with a pyrophosphate. The more important distinguishing tests for the three acids or acidic soln. of the salts of the acids are summarized in Table VII. The reactions with silver nitrate, barium chloride or nitrate, and albumen are the more important.

Table VII.—Some Reactions of the Phosphoric Acids.

——	Orthophosphoric acid.	Pyrophosphoric acid.	Metaphosphoric acid.
Silver nitrate . . .	Yellow pp.	White cryst. pp.	White gel.
Barium chloride . .	No pp. In alkaline soln. white pp.	No pp. In alkaline soln. white pp.	White pp.
Albumen . . .	Nil.	Nil.	White pp.
Zinc acetate . . .	Nil.	White pp.	Nil.
Ammonium molybdate in nitric acid	Citron-yellow pp.	Nil.	Nil.
Luteocobalt chloride .	No immediate pp.	Reddish-yellow pp.	No immediate pp.
Aluminium salts . .	Pp. soluble in acetic acid.	Pp. insoluble in acetic acid.	Pp. insoluble in acetic acid.
Chromium salts . .	Ibid.	Ibid.	Ibid.
Cobalt salts . . .	Blue; soluble in acetic acid.	Red; insoluble in acetic acid.	Red; insoluble in acetic acid.
Bismuth salts in alkaline soln.	Nil.	Nil.	White pp.

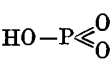
§ 27. The Polymetaphosphoric Acids and their Salts

Metaphosphoric acid forms a number of salts which have the same percentage composition—one equivalent of monobasic acid to one of mono-acid base—but, when prepared in different ways their properties are so different that it does not appear likely that they can be referred to the same parent acid. The nature of these differences is not very clear; and E. Cornec[1] said that *ces sels constituent un des chapitres obscurs de la chimie minérale.* T. Fleitmann regarded the differences as the result of different polymerized forms of the monobasic acid, and he postulated a series of metaphosphoric acids formed by the union of 1, 2, 3, . . . mols. of water with 1, 2, 3, . . . mols. of phosphoric anhydride—*e.g.* monometaphosphoric acid: $H_2O+P_2O_5=H_2P_2O_6$, or $(HPO_3)_2$; $2H_2O+2P_2O_5=H_4P_4O_{12}$, or $(HPO_3)_4$; etc. The polymetaphosphoric acids can be regarded as forming a series of homologues with the general formula: $mH_3PO_4—mH_2O$, or $(HPO_3)_n$, where m ranges from 1 to 5, or even to 8, 10, and 14.

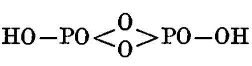
HPO_3, Monometaphosphoric acid.	$NaPO_3$, Sodium metaphosphate.
$(HPO_3)_2$, Dimetaphosphoric acid.	$K_2P_2O_6$, Potassium dimetaphosphate.
$(HPO_3)_3$, Trimetaphosphoric acid.	$Na_3P_3O_9$, Sodium trimetaphosphate.
$(HPO_3)_4$, Tetrametaphosphoric acid.	$Pb_2P_4O_{12}$, Lead tetrametaphosphate.
$(HPO_3)_4$, Pentametaphosphoric acid.	$(NH_4)_5P_5P_{15}$, Ammonium pentametaphosphate.
$(HPO_3)_6$, Hexametaphosphoric acid.	$Na_6P_6O_{18}$, Sodium hexametaphosphate.

The graphic formulæ for the parent acids may be represented in at least two ways:



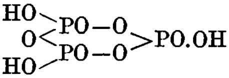
$$HO-P\begin{smallmatrix}\lessgtr\end{smallmatrix}^{O}_{O}$$

Monometa-
phosphoric acid.



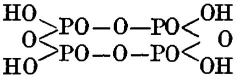
$$HO-PO<^{O}_{O}>PO-OH$$

Dimetaphosphoric
acid.



$$\begin{matrix}HO\searrow & PO-O & \\ O< & & >PO.OH \\ HO\nearrow & PO-O & \end{matrix}$$

Trimetaphosphoric
acid.



$$\begin{matrix}HO\searrow & PO-O-PO<^{OH} \\ O\lessgtr & \quad\quad\quad O \\ HO\nearrow & PO-O-PO<_{OH}\end{matrix}$$

Tetrametaphosphoric
acid.

Again, by adding tervalent groups —O.PO= to the phosphorus atom of metaphosphoric acid, graphic formulæ for the more complex metaphosphoric acids can be obtained:

$$HO-P\begin{smallmatrix}\lessgtr\end{smallmatrix}^{O}_{O}$$

Monometa-
phosphoric acid.

$$PO_2-OPO<^{OH}_{OH}$$

Dimetaphosphoric
acid.

$$PO_2-O.PO<^{OH}_{O.PO=(OH)_2}$$

Trimetaphosphoric
acid.

$$PO_2-O.PO<^{O.PO=(OH)_2}_{O.PO=(OH)_2}$$

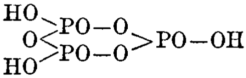
Tetrametaphosphoric
acid.

There is no definite evidence in favour of these or indeed of other possible explanations of the constitution of these acids. Indeed, the evidence as to their chemical individuality is not above suspicion. Only the salts, not the acids, are known.

Monometaphosphates.—By heating microcosmic salt, $(NH_4)NaHPO_4$, on a gradually rising temp., T. Fleitmann and W. Henneberg, obtained results similar to those previously obtained by T. Graham, first disodium dihydrogen pyrophosphate, and then a vitreous cake, which, when treated with an excess of water formed what are called *Graham's soluble salt* and *Graham's insoluble salt*—both are modifications of sodium metaphosphate. T. Fleitmann and W. Henneberg separated what they considered to be sodium trimetaphosphate from the soluble portion; while the insoluble part—called *Maddrell's insoluble salt*—was supposed to be sodium monometaphosphate. A similar salt was prepared by R. Maddrell from alkali nitrate and phosphoric acid; and the same salt is supposed to be generally obtained by heating an alkali oxide with an eq. amount of phosphoric acid to a red-heat (but not high enough to melt the mass) until the residue does not give an acid reaction. The portion which remains when the product is leached with water is supposed to be the salt in question. T. Fleitmann was unable to make any double salts with the monometaphosphate. It is not yet proved that the constitution of these salts is really that postulated by T. Fleitmann and W. Henneberg. When the sodium salt is digested for some weeks with a soln. of potassium or ammonium chloride, it furnishes the corresponding potassium or ammonium salt—$2KPO_3.3H_2O$, or $5NH_4PO_3.6H_2O$. According to G. Tammann, these salts may be regarded as α-**monometaphosphates,** another isomeric series of monometaphosphates is formed by neutralizing a soln. of metaphosphoric acid with alkali carbonate, whereupon $Na_2HPO_4.12H_2O$ separates, and the mother-liquid, at 50°, furnishes microscopic crystals of what G. Tammann called β-**monometaphosphate,** which when compressed and dried on earthenware slabs have a composition corresponding with $NaPO_3.1\frac{1}{2}H_2O$. When moist, this salt quickly passes into the orthophosphate. Potassium and ammonium monometaphosphates are formed in a similar manner. If R. Maddrell's insoluble salt be heated to redness, it melts to a colourless fluid, which, on cooling, forms a transparent glass—*Graham's salt.* For the preparation of an aq. soln. of monometaphosphoric acid, *vide supra.* P. Pascal argued that the salts and acids formed at a high temp. are highly polymerized, and he prepared the monometaphosphate by the action of ethyl hexametaphosphate on sodium ethoxide in alcoholic soln. The reaction is violent, and yields a yellow, sticky mass: $(C_2H_5PO_3)_6+6C_2H_5ONa=6(C_2H_5)_2NaPO_4$; and $(C_2H_5)_2NaPO_4=NaPO_3+(C_2H_5)_2O$. When washed with warm alcohol, the sodium salt obtained in a 30–40 per cent. yield is in the form of small, colourless, deliquescent grains. Its neutral soln. gives white salts with lead, silver, and barium salts; leuteocobalt chloride gives no reaction for pyrophosphates; its soln. in acetic acid coagulates albumen. The f.p. method shows that its mol. wt. is in agreement with $NaPO_3$, and is the same as that prepared at 250°, and 300°. P. Pascal found that the insoluble alkali monometaphosphates of T. Graham, and R. Maddrell are soluble in soln. of the pyrophosphates, even $0{\cdot}1N$-soln., and they are really complexes of high mol. wt. Only the salts prepared by P. Pascal at a low temp. are truly monometaphosphates. J. Müller described some of these salts. P. Pascal gave 333×10^{-7} mass units for the mol. magnetic susceptibility of the PO_3-radicle of sodium salt.

Dimetaphosphates.—The acid itself has not been isolated, but A. Glatzel obtained an aq. soln. of **dimetaphosphoric acid,** $H_2P_2O_6$, by decomposing the silver salt in water by hydrogen sulphide. The soln. is unstable, and soon forms pyrophosphoric and orthophosphoric acids—particularly if heated. The soln. has acidic reactions, and when neutralized with alkali-lye gives a salt identical with that prepared in other ways. The dimetaphosphates were prepared by T. Fleitmann and W. Henneberg, R. Maddrell, and G. von Knorre, by heating an excess of phosphoric acid with the oxide, nitrate, or other salt of copper, manganese, zinc, or cobalt between 316° and 400°. The metals with a high at. wt.—*e.g.* barium, lead, cadmium, silver, and bismuth—usually give hexametaphosphates by this treatment; nickel and magnesium salts do not react in the same way. According to A. Glatzel, if, say, the zinc salt be treated with potassium sulphide, a soluble *potassium dimetaphosphate,* $K_2P_2O_6.H_2O$, is formed; with sodium sulphide, the corresponding *sodium dimetaphosphate,* $Na_2P_2O_6.2H_2O$, and with ammonium sulphide, *ammonium dimetaphosphate,* $(NH_4)_2P_2O_6$, is obtained. The other dimetaphosphates are obtained by double decompositions—*e.g.* chromium, ferric, nickel, cobalt, magnesium, barium, strontium, calcium, silver, lead, zinc, copper, etc. Of these salts, there are $MP_2O_6.4H_2O$, where M represents Cu, Zn, or Mn; and $M_2P_2O_6.2H_2O$, where M represents Na, Li, Pb, Ba, or Ca. The ammonium and silver salts are anhydrous; and the magnesium salt corresponds with $MgP_2O_6.4\frac{1}{2}H_2O$. Aluminium metaphosphate, $Al_2(P_2O_6)_3.nH_2O$, is also typical of the chromic and ferric salts, but whether these salts are really dimetaphosphates or not is an open question. The alkali salts are readily soluble in water, and crystallizable; the other salts are sparingly soluble in water. The less soluble salts are but little attacked by dil. hydrochloric or nitric acid, but boiling conc. sulphuric acid decomposes them completely, forming orthophosphates. The mol. wt. of the ammonium salt from the f.p. of aq. soln. is 118, the calculated value for $(NH_4)_2P_2O_6$ is 97. The ammonium salt is isomeric with hydrazine hypophosphate, $(N_2H_4)H_4P_2O_6$. Very conc. soln. of the ammonium salt crystallize as tetrahydrate, $(NH_4)_2P_2O_6.4H_2O$. According to T. Fleitmann, this salt passes into *ammonium monometaphosphate*, NH_4PO_3, when heated between 200° and 250°. *Copper dimetaphosphate*, $CuP_2O_6.4H_2O$, is imperfectly decomposed by hydrogen sulphide. There are cogent reasons for doubting the existence of the dimetaphosphates as chemical individuals. P. Pascal believed that the so-called dimetaphosphates are tetrametaphosphates; he gave 325×10^{-7} mass units for the mol. magnetic susceptibility of the PO_3 radicle of R. Maddrell's sodium salt. He found the change in diamagnetism with increasing complexity in the series of polymetaphosphates, is in the same direction and of the same order or magnitude as that caused by double bonds in organic compounds. This is in agreement with the view that R. Maddrell's salt is truly a dimetaphosphate. G. Tammann suggested they are really trimetaphosphates. An application of the electrolysis rule to soln. of the dimetaphosphates leads to the conclusion that the dimetaphosphates in aq. soln. at any rate, are salts of a tetrabasic acid, and hence F. Warschauer argued that T. Fleitmann's dimetaphosphates are really tetrametaphosphates. A. Holt and J. E. Myers failed to obtain the dimetaphosphates by the above process, and they conclude that the so-called alkali dimetaphosphates are "probably mixtures of the alkali salts and phosphoric acids, and not definite compounds." A. Glatzel reported about thirty complex double salts of the alleged dimetaphosphates of the general formula $M'_2M''P_2O_6.nH_2O$—*e.g.* $K_2Zn(P_2O_6)_2.6H_2O$; $K_2Cu(P_2O_6)_2.4H_2O$, etc.—from soln. containing eq. proportions of the two dimetaphosphates.

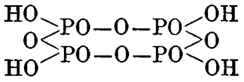
Trimetaphosphates.—T. Fleitmann and W. Henneberg prepared the sodium trimetaphosphate by heating sodium ammonium phosphate until the fused mass became crystalline. When extracted with water, insoluble monometaphosphate —R. Maddrell's salt—remains and the aq. soln. furnishes crystals of *sodium trimetaphosphate*, $Na_3P_3O_9.6H_2O$. Several other modes of preparation have been described, *e.g.* by G. Tammann, S. Tanatar, G. von Knorre, and L. Jawein and A. Thillot. A. Jamieson prepared it by heating sodium pyrophosphate with ammonium chloride: $Na_4P_2O_7+2NH_4Cl=2NaPO_3+2NH_3+2NaCl+H_2O$. According to G. von Knorre, the best method of preparation is to digest a mixture of disodium hydrogen phosphate, $Na_2HPO_4.12H_2O$, and ammonium nitrate, NH_4NO_3, in the proportion 1:3, for about 6 hrs. at 300°, and allow the clear aq. extract to crystallize. According to T. Fleitmann and W. Henneberg, sodium dimetaphosphate is obtained by heating sodium dihydrogen phosphate, although from determinations of the depression of the f.p., G. Tammann believed that the salt obtained by this process is a dimetaphosphate. P. Pascal gave 315×10^{-7} mass units for the mol. magnetic susceptibility of the PO_3-radicle of sodium trimetaphosphate. The sodium salt can be purified from pyro- and hexametaphosphates by first converting it into *lead trimetaphosphate*, $Pb_3P_3O_9.3H_2O$, by allowing a mixed soln. of the sodium salt and lead nitrate (not acetate) to stand for some days. The lead salt can be decomposed by digestion with sodium sulphate, and the sodium trimetaphosphate obtained in triclinic crystals of sp. gr. 2·476. The salt reacts like a neutral salt, with methyl-orange and phenolphthalein. The salt loses most of its water of crystallization over conc. sulphuric acid, or when heated on a water-bath; it is soluble in water, and very sparingly soluble in alcohol. According to A. Wiesler, the sodium salt is not converted into pyro- or ortho-phosphate when its aq. soln. is boiled, although S. Tanatar said that it is converted into pyrophosphate if allowed to stand for some time. *Silver trimetaphosphate*, $Ag_3P_3O_9.H_2O$, can be prepared in a similar manner to the lead salt, and most of the metal trimetaphosphates can be made by the action of the metal chloride or sulphate on the sodium salt. A soln. of free **trimetaphosphoric acid**, $H_3P_3O_9$, was prepared by A. Wiesler by the double decomposition of the silver salt or the lead salt. The acid is fairly stable in the cold, but is rapidly hydrolyzed to the normal ortho-acid on evaporation. C. G. Lindbom represented the constitution of the tribasic acid:



$$\begin{array}{l} HO \\ O \\ HO \end{array}\!\!\begin{array}{l} >PO-O \\ < \\ >PO-O \end{array}\!\!>PO-OH$$

The electrical conductivities of the sodium salt, by G. von Knorre, F. Warschauer, and G. Lammann, are in agreement with the tribasicity of the acid. S. Tanatar gave 15·15 Cals. for the heat of neutralization, $H_3P_3O_9+NaOH$. All the trimetaphosphates—even the silver and barium salts—are soluble in water. The potassium and ammonium salts are anhydrous; the manganese, cobalt, zinc, and copper salts crystallize with 9 mols. of water; the manganese salt also forms $Mn_3(P_3O_9)_2.11H_2O$; the ferrous salt, $Fe_3(P_3O_9)_2.12H_2O$; magnesium forms both $Mg_3(P_3O_9)_2.12H_2O$ and $Mg_3(P_3O_9)_2.15H_2O$. The trimetaphosphates readily form double salts—*e.g.* the double salt *calcium sodium trimetaphosphate*, $NaCaP_3O_9.3H_2O$, crystallizes from a mixed soln. of the sodium salt and calcium chloride; this and the other members of the series have the type formula $R''R'P_3O_9.nH_2O$, where R'' represents an atom of barium, strontium, or calcium, and R' an atom of sodium or potassium, or NH_4-radicle. Another series of double salts has the type formula $R''Na_4(P_3O_9)_2.nH_2O$, when R'' denotes an atom of cobalt, nickel, or cadmium. The salt $NiNaP_3O_9.4\frac{1}{2}H_2O$ has also been reported. The trimetaphosphates are perhaps better characterized than any of the salts of the other polymetaphosphoric acids; they all crystallize; and they are recognized by forming no precipitates with barium chloride or silver nitrate. P. Pascal agrees that the trimetaphosphates of A. Wiesler are correctly named.

Tetrametaphosphates.—T. Fleitmann prepared what he called tetrametaphosphates in colloidal masses by heating mixtures of the orthophosphates of the heavy metals with an excess of phosphoric acid at about 300°; according to A. Glatzel, salts or oxides may be used in place of the phosphate, and the calcination is made at a red-heat. In either case, the mass is extracted with water. When the product is digested with sodium or potassium sulphide, small crystals of the sodium or potassium salt are obtained. The electrical conductivity of the aq. soln. of the sodium salt corresponds with that required for a tetrabasic acid. The alkali salts prepared at the higher temp. form gum-like masses which do not pass through a filter-paper; while the alkali salts prepared at the lower temp. form crystals on evaporating the aq. soln., but not if precipitated by the addition of alcohol. The salts prepared at the higher temp. are thought to be hexametaphosphates. P. Pascal gave 298×10^{-7} mass units for the mol. magnetic susceptibility of the PO_3-radicle of sodium tetrametaphosphate. T. Fleitmann is reported to have made double salts by fusing mixtures of his copper and sodium dimetaphosphates —*e.g.* copper and sodium dimetaphosphates gave him $CuNa_2P_4O_{12}$. Tetrametaphosphates were also prepared by A. Glatzel, F. Warschauer, G. von Knorre, and G. Tammann. The first-named found the electrical conductivities of some of the salts fit in well with their tetrabasicity. G. Tammann said that the salts are hexa- or dodeca-metaphosphates; but P. Pascal considered that the tetrametaphosphates of F. Warschauer, and G. Tammann are correctly named. The aq. soln. of tetrametaphosphoric acid, $H_4P_4O_{12}$, was made by A. Glatzel, and F. Warschauer by treating the insoluble metal salts—*e.g.* those of silver or lead—suspended in water with hydrogen sulphide. The aq. soln. can be kept for a short time, but it rapidly passes into the pyro-acid, and finally into the ortho-acid. The products obtained by neutralizing the acid with alkali-lye are identical with those obtained in other ways. A. Glatzel represented the constitution:



Pentametaphosphates.—G. Tammann reported that he had made *ammonium pentametaphosphate*, $(NH_4)_5P_5O_{15}$, by heating ammonium dimetaphosphate at 200°–250°, and treating the resulting mass with water. The same salt is made by dissolving ammonium decametaphosphate in hot water; alcohol precipitates the salt from this soln. in white amorphous masses which have not been obtained in the crystalline state, but if the soln. be evaporated on a clock glass a stellate film is formed. G. Tammann measured the electrical conductivities of the soln. When this salt is treated with potassium bromide, **ammonium potassium pentametaphosphate**, $K_4(NH_4)P_5O_{15}.6H_2O$, separates from the soln.; similarly, sodium or lithium chloride gives an analogous **ammonium sodium pentametaphosphate**, $Na_4(NH_4)P_5O_{15}$, or **ammonium lithium pentametaphosphate**, $Li_4(NH_4)P_5O_{15}$. The potassium salt furnishes a crystalline mass, the others form gum-like masses on evaporating the aq. soln. There are several other differences between the potassium and ammonium salts—$K_4(NH_4)P_5O_{15}$ and $(NH_4)_4(NH_4)P_5O_{15}$—and the sodium and lithium salts—$Na_4(NH_4)P_5O_{15}$ and $Li_4(NH_4)P_5O_{15}$. For instance, the behaviour of the two series of salts towards reagents is not quite the same; and the electrical conductivities of the lithium and sodium salts agree with the assumption that each salt furnishes five cations, while the other salts furnish one cation, and thus behave like salts of a monobasic acid. It is therefore inferred that $[M_4P_5O_{15}]'$ behaves as a monobasic complex ion, an inference which is confirmed by the subtitutions just indicated. By treating the ammonium salt with silver nitrate, a pulverulent salt with the empirical composition $AgPO_3.\frac{1}{2}H_2O$ is obtained. When this is treated with the ammonium salt, it furnishes a crystalline product, $Ag_4(NH_4)P_5O_{15}.2H_2O$. Solutions of the sodium and lithium salts (1) give no precipitates with mercuric or cadmium chlorides, or with cupric sulphate—although the ammonium salt does give a gum-like mass; (2) with barium or ferric chloride and lead nitrate, precipitates are formed which are insoluble in an excess of reagent, (3) strontium chloride, or bismuth or silver nitrate gives a flocculent precipitate soluble in an excess of reagent; and (4) calcium chloride, or nickel, cobalt, manganese, zinc, ferrous, or aluminium sulphate gives a gum-like separation or a flocculent precipitate. The solubilities of these precipitates in an excess of their components indicates the formation of complex salts. The free acid has not been made.

Hexametaphosphates.—H. Lüdert prepared *sodium hexametaphosphate* by gradually heating disodium hydrogen pyrophosphate to a red-heat, and rapidly cooling the fused mass; it is also made by fusing monosodium hydro-orthophosphate, or microcosmic salt, so that T. Graham's salt is considered to be more or less impure sodium hexametaphosphate. T. Fleitmann considered that T. Graham's salt is a hexametaphosphate, since five of the sodium atoms can be replaced by ammonium, forming a substance with the empirical composition $(NH_4)_5NaP_6O_{18}$, but he did not prove that the fused salt is not a mixture of sodium monometaphosphate or of some other metaphosphate with a different polymeric form. G. Rose showed that soln. of T. Graham's salt furnish precipitates partly flocculent and partly gelatinous, when mixed with many salts of the metals or alkaline earths, *e.g.* by pouring the freshly prepared soln. into an excess of silver nitrate, two distinct layers are formed: (*a*) a crystalline salt, and (*b*) a gelatinous or resinous layer which is insoluble in water, and which appears to have the composition $Ag_5NaP_6O_{18}$. The crystalline salt is probably *silver hexametaphosphate*, $Ag_6P_6O_{18}$, which when treated with sodium chloride furnishes *sodium hexametaphosphate*, $Na_6P_6O_{18}$; and when this is digested with ammonium chloride, a salt, $(NH_4)_5NaP_6O_{18}$, is formed. Hence, G. Tammann obtained sodium hexametaphosphate from Graham's salt by first producing the crystalline silver salt, and then converting it into the sodium salt by treatment with sodium chloride. T. Fleitmann said that the acid itself can be made by calcining orthophosphorous acid. H. Lüdert obtained it by treating with hydrogen sulphide the lead or silver salt suspended in water. The aq. soln. is very unstable, and is readily hydrated, and, as A. Wiesler said, gives no information as to the basicity of the acid. G. Tammann believed that the sodium salt is really a mixture of $Na_6(PO_3)_6$ and two other hexametaphosphates, $Na_5[Na(PO_3)_6]$, and $Na_4[Na_2(PO_3)_6]$. This is inferred from the electrical conductivities of $K_2Na_4(PO_3)_6$ and $Na_2Na_4(PO_3)_6$, which show that two of the atoms of the alkali metal per mol are ionized. The salts may be *bis*-hexametaphosphates or *tris*hexametaphosphates, but probably are hexametaphosphates. The so-called a-monometaphosphoric acid may be identical with hexametaphosphoric acid. A. Wiesler prepared some of these salts. P. Pascal gave 289×10^{-7} mass units for the mol. magnetic susceptibility of the PO_3-radicle in T. Graham's sodium hexametaphosphate.

P. Pascal prepared *ethyl hexametaphosphate*, $(C_2H_5PO_3)_6$, by treating phosphoric oxide with absolute alcohol for some hours at the boiling temp., or some months at room temp. The viscous liquid is insoluble in ether, but soluble in chloroform. When fractionally precipitated by ether from its soln. in chloroform, about 12 per cent. of a polymer insoluble in chloroform is obtained. Ethyl hexametaphosphate has the mol. wt. required for $(C_2H_5PO_3)_6$, when its effect on the f.p. of naphthalene is determined. It gives sodium monometaphosphate when treated with sodium ethoxide. The alkali hexametaphosphates are best prepared by fusing the trimetaphosphate in small portions at a time in a platinum crucible at about 700°, and rapidly cooling the fused mass by plunging the bottom of the crucible in cold water. The transition temp. to the trimetaphosphate is 607°±2°. The change from the tri- to the hexa-metaphosphate is almost instantaneous, but the reverse change decreases rapidly with fall of temp., and is practically zero below 500°. The hexametaphosphates at a high temp. gradually become colloidal, as shown by the viscosity of the soln. There is a limit, 1·8 per cent. of colloid at 648° in 16 hrs.; and 1·2 per cent. in 6 hrs. at 835°. The hexametaphosphates are distinguished by forming complexes with iron and uranyl resembling the ferro- and ferricyanides —*e.g.* $M_4[Fe(PO_3)_6]$, $M_3[Fe(PO_3)_6]$, $M_4[UO_2(PO_3)_6]$. Consequently the hexametaphosphates decolorize ferric thiocyanate, and prevent the coloration of uranyl salts by potassium ferrocyanide. These reactions will detect the hexametaphosphates if one per cent. be present in a mixture. Graham's soluble salt behaves like a complex hexametaphosphate, $Na_2[Na_4(PO_3)_6]$. It is unstable in aq. soln., and in the presence of a lead salt precipitates lead hexametaphosphate from which the ordinary alkali hexametaphosphates can be prepared.

A number of still higher polymerized metaphosphates have been reported. According to G. Tammann, by melting a mol of a salt of a bivalent metal with a mol of sodium ammonium hydrophosphate, a clear fluid is obtained which crystallizes when the mass is cooled. The cubic or octahedral crystals have the composition of **octometaphosphates,** *e.g.* $Zn_3Na_2P_8O_{24}$—representing **octometaphosphoric acid,** $H_8P_8O_{24}$, magnesium, manganese, cobalt, nickel, or zinc sulphates may be used, but not barium, lead, or copper salts, for the latter give pyrophosphates. G. von Knorre had doubts about the chemical individuality of the octometaphosphates. By heating ammonium dimetaphosphate for two or three hours between 200° and 250°, G. Tammann prepared what he regarded as a **decametaphosphate,**

$(NH_4)_{10}P_{10}O_{30}$, which is partly changed by treatment with soln. of the metal salts—*e.g.* potassium hydroxide, or potassium chloride giving **ammonium ennea-potassium decametaphosphate,** $K_9(NH_4)P_{10}O_3.10H_2O$, as an insoluble crystalline powder. When the deca-salt is treated with hot water, two mol. eq. of pentametaphosphate are obtained. G. von Knorre had doubts about the chemical individuality of the decametaphosphates. When nickel or cobalt sulphate is melted with phosphoric acid containing some sodium salt, R. Maddrell reported that **sodium cobalt and sodium nickel tetradecametaphosphates,** $Ni_6Na_2P_{14}O_{42}$, or $Co_6Na_2P_{14}P_{42}$—representing **tetradecametaphosphoric acid,** $H_{14}P_{14}O_{42}$—are formed. G. Tammann also reported a *sodium magnesium tetradecametaphosphate*, $Na_2Mg_6(PO_3)_{14}$, but, added G. von Knorre, whether it is to be considered as a chemical individual or a mixture is open to question. P. Pascal gave for the three colloidal salts the mol. magnetic susceptibility 266×10^{-7}, 268×10^{-7}, and 268×10^{-7}, and for the non-colloidal salt 254×10^{-7}; and inferred that the colloidal salts are three forms of the octometaphosphate, and the non-colloidal salt is a decametaphosphate.

There is some doubt if some of the polymetaphosphates are really chemical individuals, and if some of the individual metaphosphates have been inserted in the right class. Decisive evidence is usually wanting, for, in spite of the many researches which have been made on the metaphosphates, their chemistry is by no means in a satisfactory condition. As F. Warschauer said in 1903, the metaphosphates form one of the most confused chapters of inorganic chemistry.

§ 28. Polyphosphoric Acids

Pyrophosphoric acid can be considered as a member of a series of polyphosphoric acids. They can be derived from ordinary phosphoric acid by the abstraction of water, thus:

Pyrophosphoric acid, $H_4P_2O_7$	$2H_3PO_4$ less H_2O
Triphosphoric acid, $H_5P_3O_{10}$	$3H_3PO_4$ less $2H_2O$
Tetraphosphoric acid, $H_6F_4O_{13}$	$4H_3PO_4$ less $3H_2O$

The general formula is $mH_3PO_4-(m-1)H_2O$, or $H_nP_{n-2}O_4+(n-3)_3$. For example:

Orthophosphoric acid ($m=1$)	H_3PO_4
Di- or pyro-phosphoric acid ($m=2$)	$H_4P_2O_7$
Triphosphoric acid ($m=3$)	$H_5P_3O_{10}$
Tetraphosphoric acid ($m=4$)	$H_6P_4O_{13}$

Salts of some of these acids were made by T. Fleitmann and W. Henneberg,[1] P. Glühmann, F. Schwarz, and M. Stange, by heating metaphosphates with pyro- or ortho-phosphates. On cooling a fused mixture of anhydrous sodium pyrophosphate (100 parts) with sodium metaphosphate (50 parts) which has been kept at a bright red-heat for about half an hour, a crystalline mass of sodium triphosphate, $Na_5P_3O_{10}$, is obtained: $Na_4P_2O_7+NaPO_3=Na_5P_3O_{10}$. The conc. aq. soln. furnishes crystals corresponding with $Na_5P_3O_{10}.8H_2O$—a result not obtained by simply evaporating a soln. of the two salts in water, and which has been used against the argument that the alleged triphosphate is a double salt of sodium pyro- and meta-phosphates. The aq. soln. when boiled decomposes into a mixture of the two components. Various double salts have been prepared of the type $M''Na_3P_3O_{10}$, by treatment with cobalt, zinc, and other salts. Zinc and manganese salts of the type $M''_2NaP_3O_{10}$ have been made. M. Stange found that when titrated with 1 : 10 soln. of ferrous ammonium sulphate, lead nitrate, manganese sulphate, cadmium sulphate, or barium chloride rather more liquid is required to produce a precipitate with a soln. of triphosphate than with an eq. mixture of meta- and pyro-phosphates; rather less with a soln. of chrome-alum, and just the same with silver nitrate. F. Schwarz claims to have made the free acid —**triphosphoric acid,** $H_5P_3O_{10}$—by treating an aq. soln. of the copper salt with hydrogen sulphide. The aq. soln. of the acid is soon transformed into pyrophosphoric acid, $2H_5P_3O_{10}+H_2O \rightarrow 3H_4P_2O_7$, and albumen is not coagulated; if, however, the sodium salt is treated with a few drops of acetic acid, the albumen is coagulated. F. Schwarz represented the constitution

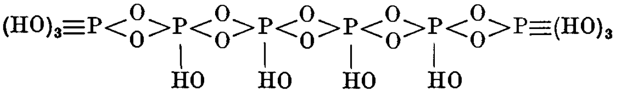
$$\left.\begin{matrix}(HO)_2=PO.O\\(HO)_2=PO.O\end{matrix}\right> PO-OH$$

in agreement with the phenyl triphosphate obtained by M. Riegel.

T. Fleitmann and W. Henneberg also prepared *sodium tetraphosphate*, $Na_6P_4O_{13}$ —representing **tetraphosphoric acid,** $H_6P_4O_{13}$—by melting together a mixture of eq. amounts of sodium hexametaphosphate, $Na_6P_6O_{18}$, and sodium pyrophosphate: $Na_6P_6O_{18}+3Na_4P_2O_7=3Na_6P_4O_{13}$; or with sodium orthophosphate: $Na_6P_6O_{18}+2Na_3PO_4=2Na_6P_4O_{13}$. Sodium tetraphosphate can be crystallized from its soln. in hot water, although it is slowly transformed into the orthophosphate in warm aq. soln. An acid salt has not been made, but silver and magnesium salts of a similar composition have been made by double decomposition of the sodium salt with salts of the respective elements. If sodium salts were those of a hexametaphosphate, they should give no precipitate with magnesium salts, and with silver salts a precipitate soluble in an excess of the sodium salt. C. F. Gerhardt thought the salt crystallizing with 18 mols. of water of crystallization to be an acid salt of pyrophosphoric acid, but K. Kraut and H. Uelsmann found that this is not likely to be the case because all the water is lost in a desiccator over sulphuric acid. M. A. Rakusin and A. A. Arsenéeff found that after the violent reaction resulting from the addition of phosphoric oxide to water and formation of orthophosphoric acid has subsided, further quantities are gradually added until the amount reaches about 520 per cent. of the water present. After keeping for five days, crystals of tetraphosphoric acid, $H_6P_4O_{13}$, separate from the syrupy liquid. This acid has previously only been prepared in the form of its salts. The acid melts at 34°, and has a sp. gr. of 1·8886 at 15°.

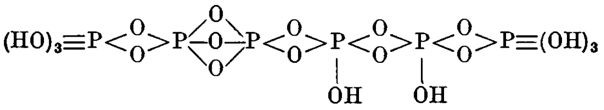
T. Fleitmann and W. Henneberg also prepared **sodium decaphosphate,** $Na_{12}P_{10}O_{31}$,—representing **decaphosphoric acid,** $H_{12}P_{10}O_{31}$—by fusing together eq. quantities of sodium hexametaphosphate and sodium pyrophosphate: $4Na_6P_6O_{18}+3Na_4P_2O_7=3Na_{12}P_{10}O_{31}$.

A. V. Kroll[2] reported a series of salts which he called *ultra-phosphates*, but the following is not his view of their nature. Assuming the ultra-phosphates are chemical individuals, they can be derived from the **orthohexaphosphoric acid,** $H_{20}P_6O_{25}$, or $(HO)_4P.O.P(OH)_3.O.P(OH)_3.O.P(OH)_3.O.P(OH)_3.O.P(OH)_4$, by the loss of five mols. of water so as to form **penterohexaphosphoric acid,** $H_{10}P_6O_{20}$, represented by **calcium penterohexaphosphate,** $5CaO.P_2O_5$, or $C_5P_6O_{20}$—for the nomenclature, *vide* the silicic acids, **6.** 40, 22.

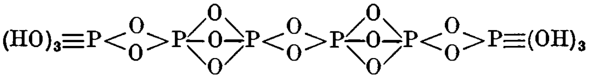


$$(HO)_3\equiv P{<}{}^{O}_{O}{>}\underset{\displaystyle HO}{\underset{|}{P}}{<}{}^{O}_{O}{>}\underset{\displaystyle HO}{\underset{|}{P}}{<}{}^{O}_{O}{>}\underset{\displaystyle HO}{\underset{|}{P}}{<}{}^{O}_{O}{>}\underset{\displaystyle HO}{\underset{|}{P}}{<}{}^{O}_{O}{>}P\equiv(HO)_3$$

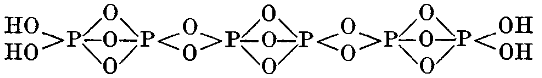
is obtained as a fused mass by passing the vapour of phosphoric oxide over heated lime; lead oxide furnishes the corresponding lead salt; and magnesium and nickel salts have been made. The tetrabasic phosphate, Thomas' slag, **calcium hexerohexaphosphate,** $4CaO.3P_2O_5$, and the lead salt, $4PbO.3P_2O_5$, representing the **hexerohexaphosphoric acid,** $H_8P_6O_{19}$:



The next member of the series would be **hepterohexaphosphoric acid,** $H_6P_6O_{18}$:



which is isomeric with hexametaphosphoric acid, and represented by the hydrate, $2Na_2O.3P_2O_5.H_2O$, or $Na_4H_2P_6O_{18}$. When the vapour of phosphorus pentoxide acts on lime at 250°, the resulting **calcium octerohexaphosphate,** $2CaO.3P_2O_5$, or $Ca_2P_6O_{17}$, representing **octerohexaphosphoric acid,** $H_4P_6O_{17}$:



Corresponding lead, lithium, and sodium salts have been prepared. The last member of this series of salts is represented by the lithium, sodium, silver, and lead salts, $R_2O.3P_2O_5$, corresponding with **ennerohexaphosphoric acid,** $H_2P_6O_{16}$;

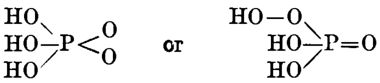
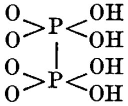
§ 29. Perphosphoric Acids

Orthophosphoric acid does not react with hydrogen dioxide, and there are no signs of the formation of a perphosphoric acid, analogous with persulphuric acid, when soln. of phosphoric acid are electrolyzed. J. Schmidlin and P. Massini,[1] and J. d'Ans and W. Friederich found the case to be different, however, if phosphorus pentoxide be treated with 30 per cent. hydrogen dioxide at low temp., for when the mixture is diluted with ice-cold water, a soln. is obtained which has oxidizing properties analogous to those possessed by permonosulphuric acid. If a dil. soln. of phosphoric acid containing hydrogen dioxide be electrolyzed, permonophosphoric acid is also obtained. Analyses correspond with **permonophosphoric acid,** H_3PO_5, or $PO(OH)_2O.OH$. A similar compound is obtained with meta- and pyro phosphoric acids; in the latter case, also, a small quantity of **perdiphosphoric acid,** $H_4P_2O_8$, is formed, particularly if the pyrophosphoric acid be in excess. The compositions of the permonophosphoric and permonosulphuric acids are different since the sulphur in the one case is sexivalent, and the phosphorus in the other case is quinquevalent:



Permonophosphoric acid.



Perdiphosphoric acid.

The proportion of $H_4P_2O_8$ which is formed is greater the greater the excess of pyrophosphoric acid over the hydrogen dioxide; for example, with 3 c.c. of dioxide to 25 c.c. of syrupy pyrophosphoric acid, the acid formed corresponded with 20 per cent. active oxygen, and with 40 per cent. active oxygen when the respective proportions were 1 : 42. Permonophosphoric acid oxidizes manganous salts to permanganates in the cold, a reaction not shown by Caro's acid, and it liberates iodine from potassium iodide. No salts—permonophosphates—have been obtained, although soln. (not acidic soln.) give precipitates with silver, iron, nickel, manganese, and salts of the heavy metals, and these rapidly change to orthophosphates with the evolution of ozonized oxygen. Conc. soln. have a smell resembling that of bleaching powder; they do not keep so well as more dil. soln. Neutral and alkaline soln. are less stable than acidic soln. G. I. Petrenko reported **sodium perphosphate,** $(NaO)PO(O_2Na)_2.6\frac{1}{2}H_2O$, as a result of treating a soln. of sodium phosphate with hydrogen dioxide; it is thought to be sodium phosphate with hydrogen dioxide of crystallization, $Na_3PO_4.2H_2O_2.4\frac{1}{2}H_2O$; and E. Pinerua-Alvarez prepared a compound $NaPO_4$ by the action of a soln. of sodium dioxide in aq. alcohol on sodium phosphate. A. R. y Miro obtained perphosphates by the electrolytic oxidation of phosphates with an electrolyte containing fluorides; the anodic oxidation of phosphates was also studied by F. Fichter and J. Müller; and the oxidation of phosphoric acid (*q.v.*) by fluorine, by F. Fichter and W. Bladergroen. S. Aschkenasy made the **alkaline earth perphosphates** by dissolving the peroxides in an excess of phosphoric acid; on evaporating the soln. under diminished press., the perphosphate is produced. If an alkali sulphate be added to the liquid before evaporation, the filtrate furnishes an **alkali perphosphate.** F. H. Fuhrmann summarized the patent literature on the subject.

§ 30. Phosphorus Fluorides

Phosphorus unites directly with the halogens in at least two different proportions—three, the fluorides, chlorides, and bromides, are of the types, PX_3 and PX_5, while the iodides are PI_3 and P_2I_4—there is also a chloride corresponding with this latter compound. The pentahalides are obtained by treating the trihalides with more halogen; the reaction is reversible, and the vapour of the pentahalide is more or less dissociated: $PX_5=PX_3+X_2$. The affinity of phosphorus for the halogens decreases with increasing at. wt.—*e.g.* the pentafluoride is the most stable higher compound, and the pentaiodide, if it has been prepared at all, is a very unstable product; the heats of formation of the trihalides decrease in the same direction:

	PF_3	PCl_3	PBr_3	PI_3
Heats of formation	108	76	44·8	10·5 Cals.
Boiling points .	−95°	76°	175°	decomposes
Melting points .	−160°	−111·8°	−41·5°	60°

The corresponding chemical properties, and also the physical properties, usually change more or less regularly in passing from one end of the series to the other. A number of mixed halides are also known, for instance, PF_5(gas), PF_3Cl_2(gas), PF_3Br_2(liquid), PF_3I_2(solid), etc.; there are also some oxy-halides, *e.g.* $POCl_3$, $POBr_3$, $POClBr_2$, etc., as well as $P_2O_3Cl_4$, PO_2Cl, etc.

H. Davy,[1] and J. B. A. Dumas prepared a fuming liquid resembling phosphorous chloride, PCl_3, by heating phosphorus with lead or mercuric fluoride. According to J. L. Gay Lussac and L. J. Thénard, this reaction only occurs in the presence of silica, and L. Pfaundler noticed that when the materials are heated in a glass tube, most of the phosphorus distils unchanged; only where the materials are in contact with the glass does etching and decomposition occur; and the product of the reaction is a vapour which does not condense at −20°. R. W. E. MacIvor also said that phosphorus fluoride is a gas at ordinary temp. and press. It was afterwards shown that phosphorus fluoride must be a gas at ordinary temp. and therefore the liquid obtained by H. Davy could not have been the fluoride. The nature of the fluorides of phosphorus was not clear until the advent of H. Moissan's investigations on fluorine, mainly recorded in his monograph *Le fluor et ses composés* (Paris, 1900). It is there shown that yellow or red phosphorus burns vigorously in fluorine gas; and when fluorine is led through a fluorspar tube containing a piece of dry phosphorus, the pentafluoride is formed, and if the phosphorus be in excess, some trifluoride as well as pentafluoride appears among the products of the reaction.

In 1884, H. Moissan[2] prepared **phosphorus trifluoride,** or **phosphorous fluoride,** PF_3, by heating a mixture of lead fluoride and copper phosphide to dull redness in a brass tube closed at one end, and fitted by means of a cork at the other end with a lead exit tube. This end of the brass tube is kept cool by a water-jacket. The gas was first passed through a wash-bottle containing a few c.c. of water to remove traces of hydrogen fluoride or phosphorus pentafluoride; and then dried by passage through a vessel containing sulphuric acid. The dry gas can be collected over mercury. H. Moissan also made the gas by the action of silver, zinc, or arsenious fluoride on phosphorus trichloride; and by the action of zinc fluoride on phosphorous bromide. A. Guntz made it by the action of lead fluoride on phosphorus trichloride; C. Poulenc, and H. Moissan, by the action of hydrogen at 250°, or of the metals—mercury, aluminium, tin, lead, iron, or nickel—at 180°, or of phosphorus at 120° on phosphorus dichlorotrifluoride; H. Moissan, by passing induction sparks through phosphorus pentafluoride: $PF_5=PF_3+F_2$; and A. Simon, by the electrolysis of soln. of the oxides of iron or manganese in molten calcium fluoride in the presence of carbon; the resulting carbon tetrafluoride acting on phosphorus or the metal phosphides yields phosphorus trifluoride: $2Mn_3P_2+3Mn+3CF_4=3Mn_3C+4PF_3$.

According to H. Moissan, phosphorus trifluoride is a colourless gas which does not fume in air, and which can be condensed to a colourless, mobile liquid which does not attack glass. The vapour density is 3·022, and the value calculated for PF_3 is 3·045. This formula is also in accord with H. Moissan's analysis. The mol. vol. of the gas at 0° and 760 mm. is 153·24 c.c. Phosphorus trifluoride does not change when heated to 500° for half an hour in an iron vessel, but in a glass vessel, or in the presence of silica, it decomposes very quickly: $4PF_3+3SiO_2=3SiF_4+3O_2+4P$. The amount of oxygen formed is not sufficient to convert all the phosphorus into the pentoxide. The b.p. of the liquid is −95°; and it can be frozen to a snow-white solid with a m.p. −160°. M. Berthelot obtained for the heat of formation of the gas from its elements 106·2 to 109·7 Cals. When phosphorus trifluoride is sparked in a glass tube with platinum electrodes, H. Moissan found that the spectrum shows many lines due to fluorine, to phosphorus, and to platinum. The phosphorus lines are very intense, whilst those of fluorine are feebler. The dry gas is decomposed by the electric discharge: $5PF_3=3PF_5+2P$. If a trace of moisture be present, the phosphorus deposits on the walls of the vessel, the vol. decreases, and the residue contains some silicon tetrafluoride formed by the action of hydrogen fluoride on the glass containing-vessel.

According to H. Moissan, when a mixture of phosphorus trifluoride and **hydrogen** is heated, hydrogen fluoride and phosphine are produced: $PF_3+3H_2=PH_3+3HF$. The hydrogen fluoride immediately attacks the glass, forming silicon tetrafluoride. The trifluoride does not burn in **air,** but if mixed with **oxygen,** the gas explodes, forming phosphoryl fluoride: $2PF_3+O_2=2POF_3$; and oxygen in excess of this proportion remains as an inert gas. A mixture of the gas with half its vol. of oxygen explodes vigorously when sparked, but it is not ignited by the flame of coal gas. The temp. is here not sufficiently high, for if the mouth of the gas-jar containing the mixture approaches the oxyhydrogen flame, the gas is ignited and the flame travels to the bottom of the jar. Phosphorus trifluoride reacts slowly with **water** at 20°, forming phosphorous and hydrofluoric acids; the reaction is not quite analogous to the reaction between water and phosphorus trichloride—*vide infra.* With boiling water or steam, the reaction proceeds more quickly, but not instantaneously. The trifluoride is not absorbed by dry **potassium hydroxide,** but with an aq. soln. of potassium or **sodium hydroxide,** the alkali fluoride and phosphite are produced, and not, as M. Berthelot supposed, potassium fluophosphate. The gas is slowly absorbed by aq. soln. of **potassium carbonate,** or of **barium hydroxide.** Absolute **alcohol** absorbs the gas with the development of much heat, forming an ethereal liquid which does not give off a gas when boiled. A yellow flame appears when the trifluoride comes in contact with **fluorine,** and the pentafluoride is formed; and H. Moissan, and C. Poulenc found that in contact with **chlorine,** the dichlorotrifluoride is formed; with **bromine,** the dibromotrifluoride; and with **iodine,** the dichlorotrifluoride. H. Moissan found that when **hydrogen chloride** is heated with the trifluoride, phosphine, and phosphorous chloride are formed. When the trifluoride is heated with **sulphur** vapour to 440°, no change can be detected. The dry trifluoride reacts with dry **ammonia,** forming a white flocculent mass which is immediately decomposed by water. No reaction occurs when the gas is heated with **phosphorus**; and **arsenic** can be sublimed in the gas without forming arsenic fluoride. This shows that phosphorus trifluoride is more stable than arsenic trifluoride. When phosphorus trifluoride is heated in contact with **boron,** in a glass vessel, the reaction furnishes phosphorus, boron trifluoride, and a little silicon tetrafluoride; with **silicon,** at a full red-heat, phosphorus and silicon tetrafluoride are formed: $4PF_3+3Si=3SiF_4+4P$, a reaction utilized for analyzing the gas. A. Simon represented the reaction with heated **silica**: $4PF_3+3SiO_2=3SiF_4+3O_2+4P$; and, as indicated above, the silica of **glass** is attacked in virtue of a similar reaction. If a piece of **sodium** be heated in phosphorus trifluoride confined over mercury, the metal melts, and the vol. of the gas then gradually decreases, until suddenly the metal becomes incandescent, and the whole of the gas is rapidly absorbed; with heated **copper,** the metal acquires a film of phosphide, the vol. of the gas decreases, and silicon tetrafluoride appears. A. Granger said that at a red-heat, copper dipentitaphosphide is formed. H. Moissan found that with **mercury** vapour no visible action occurs at 350°, aluminium has but a slight action even at the softening temp. of glass. This, said H. Moissan, seems remarkable because of the ease with which aluminium fluoride is prepared—the probable explanation is that a protective film of fluoride is formed on the surface of the metal. A. Granger found that the phosphorus trifluoride reacts with **iron, cobalt,** and **nickel** at a high temp., forming phosphides—the products are contaminated with fluorides, and decomposition products of the glass containing-vessel. When the gas is passed quickly over spongy **platinum** at a red-heat, phosphorus pentafluoride is formed; but if the gas is passed slowly, it is completely absorbed by the red-hot spongy platinum. H. Moissan found that soln. of **chromic acid,** or of **potassium permanganate,** rapidly decompose phosphorus trifluoride, forming phosphoric acid, etc.

In 1887, T. E. Thorpe[3] discovered **phosphorus pentafluoride,** or **phosphoric fluoride,** PF_5. He found that when arsenic fluoride is added drop by drop to phosphorus pentachloride contained in a small flask, a vigorous reaction occurs, a colourless fuming gas is given off, and arsenic chloride remains. The reaction is symbolized: $5AsF_3+3PCl_5=3PF_5+5AsCl_3$. The gas is contaminated with the vapours of arsenious fluoride and chloride. A. Guntz made the pentafluoride by the action of phosphorus pentachloride on lead fluoride; and H. Moissan made the same gas by sparking phosphorus trifluoride: $5PF_3=2P+3PF_5$; and by leading a rapid stream of phosphorus trifluoride through a heated tube of platinum sponge—yield 12–13 per cent. A fairly pure product was also obtained by the spontaneous decomposition of phosphorus trifluodibromide at 15°; in symbols: $5PF_3Br_2=3PF_5+2PBr_5$. The pentafluoride is a gas, and the pentabromide is a solid. The gas is contaminated with bromine, which can be removed by allowing it to stand in a dry flask in contact with mercury. C. Poulenc made the gas by heating phosphorus trifluodichloride to 200°–250°, or by passing an electric discharge through that gas. H. J. Lucas and F. J. Ewing obtained the pentafluoride by heating in an iron tube a mixture of 25 grms. of phosphorus pentoxide, and 55 grms. of dry calcium (not potassium) fluoride: $5CaF_2+6P_2O_5=2PF_5+5Ca(PO_3)_2$.

According to T. E. Thorpe, and H. Moissan, phosphorus pentafluoride is a colourless fuming gas with a powerful smell; it rapidly attacks the respiratory organs. It is heavy enough to be poured like carbon dioxide from one vessel to another. The gas is incombustible and a non-supporter of combustion. It can be kept over mercury for some time, but its volume gradually diminishes. According to T. E. Thorpe, the vapour density is 126 (H=2), and its formula is therefore PF_5, where phosphorus is undoubtedly quinquevalent. T. E. Thorpe found that at 7° and under a press. of 12 atm., the gas exhibits no marked deviation from the standard gas law. H. Moissan said the gas liquefies under a press. of 46 atm. at 15°, and if the press. is partially released the gas solidifies, but rapidly returns to the liquid condition. Notwithstanding the care taken in drying the gas, a certain quantity always remains unliquefied, but if the pressure is raised from 46 atm. to 125 atm. the meniscus disappears. The whole of the space above the mercury has the same index of refraction. This is the critical point, and hence it is possible by means of phosphorus pentafluoride to exhibit the liquefaction, solidification, and critical point of a gas at the ordinary temp. The gas can be condensed to a liquid boiling at —75°, and frozen to a solid melting at 83°. H. Moissan examined the spectrum of the gas in a discharge tube with platinum electrodes. There are fewer spectral lines with the pentafluoride than with the trifluoride, and this is taken as evidence of the greater stability of the former gas. If thoroughly dried, phosphorus pentafluoride is not changed by feeble electric sparks, but is decomposed ($PF_5=PF_3+F_2$) by intense electric sparks, and both the glass and the surface of the mercury are attacked by the fluorine; similarly, T. E. Thorpe, and H. Moissan found that it is not affected by feeble electric sparks if mixed with *hydrogen* or *oxygen*. T. E. Thorpe said that the pentafluoride is decomposed by *water*, forming hydrofluoric and phosphoric acids; if the gas is pure, added H. Moissan, the absorption of the gas by water is complete. If a trace of moisture is present when the gas is confined in a glass vessel, silicon tetrafluoride and phosphoryl fluoride are formed, and some of the alkali in the glass forms a fluophosphate, or phosphate. The pentafluoride is not attacked by *fluorine*, hot or cold; nor does *iodine* attack the gas at temp. up to 500°. The vapour of *sulphur* at 440° has no perceptible action. T. E. Thorpe said that the gas forms a yellow **phosphorus hemipentamminofluoride,** $PF_5.5NH_3$, when brought in contact with dry *ammonia;* this compound dissolves in water, and the soln. etches glass. E. Tassel found that phosphorus pentafluoride reacts with *nitrogen peroxide* at —10°, forming a mass of white crystals of **phosphorus dinitroxylpentafluoride,** $PF_5.N_2O_4$. The crystals of this compound fume in air; and dissociate at ordinary temp., and particularly when heated $PF_5.N_2O_4 \rightleftharpoons PF_5 + N_2O_4$; water decomposes it into nitric oxide, and nitric, phosphoric, and hydrofluoric acids; and conc. sulphuric acid liberates the pentafluoride, forming a substance which is decomposed by water, forming nitrosyl sulphate. Returning to phosphorus pentafluoride, H. J. Lucas and F. J. Ewing did not obtain isoamyl fluoride by the action of phosphorus pentafluoride on boiling dry isoamyl alcohol for $1\frac{1}{2}$ hrs. H. Moissan found that the pentafluoride attacks *platinum* sponge at a red-heat, liberating fluoride, and forming a platinum fluophosphide.

H. Schulze[4] obtained **phosphorus oxytrifluoride,** or **phosphoryl fluoride,** POF_3, by the action of phosphorus pentoxide on a fluoride; T. E. Thorpe and J. F. Hambly, by heating a mixture of phosphorus pentoxide and cryolite in a brass tube, and collecting the gas over mercury as soon as a sample is all absorbed by water; and H. Moissan, by the action of phosphorus pentoxide on anhydrous hydrogen fluoride; by sparking a mixture of 2 vols. of the phosphorus trifluoride with one vol. of oxygen, or by passing the same mixture over platinum sponge. H. Moissan also made phosphoryl fluoride by the action of phosphoryl chloride on silver or zinc fluoride contained in a brass tube fitted with a lead delivery tube: $POCl_3+3AgF=3AgCl+POF_3$. The evolution of gas begins at ordinary temp., and it is passed through a tube containing lead fluoride to remove traces of phosphoryl chloride. A. Guntz used lead fluoride in place of silver or zinc fluoride; and C. Poulenc, and H. Moissan obtained the gas by the action of water on phosphorus dichlorotrifluoride: $PF_3Cl_2+H_2O=POF_3+2HCl$. At ordinary temp., phosphoryl fluoride is a gas which fumes in air; and if thoroughly dried, does not attack glass. According to H. Moissan, and T. E. Thorpe and J. F. Hambly, its analysis corresponds with the formula POF_3, and this simple formula is also in agreement with their determinations of the vap. density. H. Moissan obtained 3·68 to 3·71 when the calculated value is 3·69 (air unity); and T. E. Thorpe and J. F. Hambly, 52·3, when the calculated value is 52·0 (H unity). H. Moissan found that the gas can be condensed to a liquid boiling at —40°; and solidified to a snow-white crystalline mass melting at —68°. When heated in a glass vessel, phosphoryl fluoride does not decompose so easily as phosphorus trifluoride, and it forms silicon tetrafluoride and an alkali phosphate. The gas is not attacked by fluorine in the cold, and water absorbs the gas with the development of heat, forming phosphoric and hydrofluoric acids; alcohol acts in an analogous way; and the gas is likewise quickly absorbed by a soln. of chromic oxide, or alkali-lye. W. Lange found that **difluo-dioxyphosphoric acid,** $POF_2.OH$, is a product of the hydrolysis of phosphoryl fluoride; and the ions of this acid are present in a soln. of phosphoric oxide in hydrofluoric acid. He also prepared **ammonium difluodioxyphosphate,** $(NH_4)PO_2F_2$.

H. Moissan[5] said that when phosphorus trifluoride is treated with water, the phosphorus is not converted into a phosphite or a phosphate, but into some compound which cannot be converted into a phosphate even by boiling with dil. nitric acid. M. Berthelot said that the heat developed by the action of water is 107·7 cals. per mol, a lower value than is the case with the corresponding chloride or bromide. This is because **hydrofluophosphorous acid,** HPF_4, is formed analogous to hydrofluoboric or hydrofluosilicic acids: $2PF_3+3H_2O=H_3PO_3+2HF+HPF_4$. The acid appears to form an **alkali fluophosphite** when treated with dil. alkali-lye. The hydrofluophosphorous acid is stable enough to resist splitting into a phosphite and fluoride by boiling with an excess of alkali-lye. If the liquid obtained by the action of the trifluoride on water be titrated with standard alkali soln., using methyl-orange as indicator, it appears as if the reaction is $5PF_3+12H_2O=11HF+4H_3PO_3+HPF_4$. The nature of the decomposition probably varies according to the conditions. The facts are also explained by assuming that a **phosphoryl monofluoride**, POF, is formed. So that the nature of the reaction has not yet been established.

Some fluophosphates obtained by H. Briegleb, and others have been discussed, 2. 20, 39. Free **monofluo-orthophosphoric acid,** $P(OH)_4F$, has not been obtained, but R. F. Weinland and J. Alfa[6] reported **potassium monofluotrihydrorthophosphate,** $P(OH)_3(OK)F$, to be formed by evaporating equimolar proportions of potassium hydrophosphate and potassium hydroxide to dryness, dissolving it in 40 per cent. hydrofluoric acid, and cooling the concentrated soln. by a freezing mixture. Colourless, lustrous plates belonging to the monoclinic system are formed; the axial ratios are $a:b:c=0{\cdot}8501:1:0{\cdot}6268$. The crystals are stable in dry air, but in moist air they lose hydrogen fluoride. The salt cannot be crystallized from water or hydrofluoric acid, and it loses hydrogen fluoride when heated. When the temp. is high enough the salt melts to a glass. It gives off hydrogen fluoride when treated with sulphuric acid. The corresponding **rubidium monofluotrihydrorthophosphate,** P(OH)(ORb)F, and **cæsium monofluotrihydrorthophosphate,** P(OH)OCs)F, have been reported.

§ 31. Phosphorus Dichloride and Trichloride

According to A. Gautier,[1] **phosphorus dichloride,** PCl_2, or perhaps P_2Cl_4, cannot be obtained by the action of the corresponding diiodide on silver chloride; but, according to A. Besson and A. Fournier, on submitting a mixture of phosphorus trichloride and hydrogen to the action of an electric discharge, a colourless liquid, holding in suspension a yellow solid, is produced. After filtration and purification by distillation under diminished pressure in an inert atmosphere, the liquid has a composition corresponding with that of phosphorus dichloride. It is a colourless, oily, and strongly fuming liquid. The fuming is not only caused by the action of moisture, but also by oxidation, and under certain conditions the liquid takes fire spontaneously. It boils, with decomposition, at about 180° at 760 mm. press., and at 95°–96° and 20 mm. press. without decomposition; it melts at —28°. It is decomposed by water with the formation of phosphorous acid and a yellow solid of indefinite composition. It decomposes slowly at the ordinary temperature, and more quickly when heated, to form phosphorus trichloride and a yellow to red solid of indefinite composition, which is possibly a mixture of amorphous phosphorus with other chlorides.

J. L. Gay Lussac and L. J. Thénard[2] about 1808, and H. Davy about 1810, prepared liquid **phosphorus trichloride,** or **phosphorous chloride,** PCl_3, by the action of chlorine on phosphorus. If the phosphorus be in excess, the liquid trichloride is formed, and if the chlorine be in excess, the pentachloride is produced as indicated in connection with the *la reaction très vive* between these two elements. H. Davy said:

> I introduced phosphorus into a receiver having a stopcock, which had been exhausted, and admitted oxymuriatic acid gas. As soon as the retort was full the phosphorus entered into combustion, throwing forth pale white flames. A white sublimate collected in the top of the retort, and a fluid as limpid as water trickled down the sides of the neck. The gas seemed to be entirely absorbed, for, when the stopcock was opened, a fresh quantity of oxymuriatic acid gas, nearly as much as could have filled the retort, entered. The same phenomenon of inflammation again took place, with similar results. Oxymuriatic acid gas was admitted until the whole of the phosphorus was consumed.

The liquid proved to be phosphorus trichloride, the solid, phosphorus pentachloride. When made by this process, the trichloride is contaminated with the pentachloride. Different ways of preparing the trichloride by the action of chlorine on yellow or red phosphorus have been devised by J. B. A. Dumas, V. Rekschinsky, C. Gräbe, A. A. Vanscheidt and V. M. Tolstopiatoff, etc.

> A layer of sand is placed at the bottom of a retort, and a current of dry carbon dioxide, or other inert gas, passed through the retort. Add, say, 100 grms. of yellow phosphorus —dried between filter-paper, and dipped successively in alcohol and in ether—then pass a current of chlorine through the apparatus while tho retort is heated with warm water. The tube delivering the chlorine should be movable, for if it is too near the phosphorus the phosphorus becomes hot and distils, forming a red crust in the upper part of the retort; while if it be too far away the action is slow, and the excess of phosphorus forms phosphorus pentachloride by a side reaction. When the action has begun, a tongue of flame projects from the tube delivering the chlorine. The retort does not then need heating. Towards the end, when the phosphorus has all disappeared, heat the retort very gently so as to drive the trichloride into the receiver. The fumes from the exit tube must be led into a stink closet or into a vessel containing sodium hydroxide. The product can be purified by adding, say, 2 grms. of yellow phosphorus and redistilling. The object of the phosphorus is to convert any pentachloride into the trichloride. J. J. Berzelius, and P. L. Dulong recommended a second distillation to remove the excess of phosphorus. Moisture must be carefully excluded.

U. J. J. Leverrier found that the trichloride is produced by the action of chlorine on phosphorus tetritoxide; and A. Besson, on phosphorus hemioxide; T. E. Thorpe and A. E. H. Tutton obtained it by the action of phosphorus pentachloride or of hydrogen chloride on phosphorous oxide: $P_4O_6+6PCl_5=6POCl_3+4PCl_3$; and $P_4O_6+6HCl=2PCl_3+2H_3PO_3$. A. Oppenheim found that it is produced when conc. hydrochloric acid is heated with phosphorus in a sealed tube at 200°: $2P+3HCl=PH_3+PCl_3$. H. Davy, and J. L. Gay Lussac and L. J. Thénard made the trichloride by passing the vapour of phosphorus over heated mercurous or mercuric chloride; and J. H. Gladstone added that a similar result is obtained with ferric and cupric chlorides, but not with lead chloride. H. F. Gaultier de Claubry observed that the trichloride is formed when sulphur monochloride is passed over phosphorus, the sulphur is set free; E. Baudrimont observed that a similar reaction occurs with selenium mono- or tetra-chloride; and P. Köchlin and K. Heumann, by the action of phosphorus on pyrosulphuryl chloride—they recommended heating sulphuryl chloride with red phosphorus in a flask fitted with a reflux condenser as a mode of preparing phosphorus trichloride: $3SO_2Cl_2+2P=2PCl_3+3SO_2$. P. P. Budnikoff and E. A. Shiloff found that calcium phosphate can be almost quantitatively converted into phosphorus trichloride by heating it with silica and charcoal as catalyst, in a current of sulphur monochloride: $4S_2Cl_2+Ca(PO_3)_2=2PCl_3+CaCl_2+3SO_2+5S$. Some silicon tetrachloride, derived from the silica, may be present.

The trichloride is formed by quite a number of metathetical reactions. In illustration, J. H. Gladstone showed that it is produced by the action of chlorine, or mercuric chloride on phosphorus tribromide or triiodide; A. Gautier, by the action of phosphorus diiodide on silver chloride: $3PI_2+6AgCl=6AgI+P+2PCl_3$; and C. Poulenc, by warming at 120° phosphorus with the dichlorotrifluoride: $3PF_3Cl_2+2P=3PF_3+2PCl_3$. J. L. Gay Lussac and L. J. Thénard said that a little trichloride is formed when glacial phosphoric acid is heated with sodium chloride; and H. Rose, when sodium hydrophosphate is heated with ammonium chloride. The trichloride is produced during the thermal dissociation of phosphorus pentachloride, and when the pentachloride is reduced by many metals, hydrogen, phosphine, etc.—*vide infra*, phosphorus pentachloride. J. Riban obtained the trichloride by reducing phosphoryl chloride with red-hot wood-charcoal; $POCl_3+C=CO+PCl_3$.

The physical properties of phosphorus trichloride.—At ordinary temp., phosphorus trichloride is a transparent, colourless, mobile, fuming liquid. H. V. Regnault[3] gave 4·7464 for the **vapour density** of phosphorus trichloride, and J. B. A. Dumas, 4·75, air unity. H. Davy's value, 1·45, for the **specific gravity** is low; H. L. Buff gave 1·6119 at 0°, 1·5971 at 10°, and 1·4712 at 76°; J. I. Pierre, 1·6162 at 0°; W. Ramsay and J. Shields found 1·5825 at 16·4°; and 1·527 at 46·2°; and G. Carrara and I. Zoppelari, 1·5941 at 11°/4°; A. Stiefelhagen, 1·613 at 18°; T. E. Thorpe, 1·61275 and 1·61294 at 94°, and 1·46845 at 75·95°. J. Timmermans estimated that the sp. gr. of the liquid at —273° is 2·11927; and at higher temp., T° K., $D=2{\cdot}11927-0{\cdot}00189994T+0{\cdot}0_6 1183T^2$. F. M. Jäger's values are indicated below. J. I. Pierre represented the volume, v, at θ° between —35° and 74·9° by $v=1+0{\cdot}001128620\theta+0{\cdot}0_6 87288\theta^2+0{\cdot}0_7 179236\theta^3$; and T. E. Thorpe, by $v=1+0{\cdot}001139370\theta+0{\cdot}0_5 166807\theta^2+0{\cdot}0_8 4012\theta^3$—when the vol. at 0° is unity. The vol. at 75·95° is 1·09827 when the vol. at 0° is unity. H. Kopp found **molecular volume** at the b.p. to be 93·9; H. L. Buff, 93·01–93·62; E. B. R. Prideaux, 93·34; E. Rabinowitsch, 93·7; and T. E. Thorpe, 93·34–93·68. A. Masson, S. Sugden, and J. A. Groshans studied the mol. vols. of the family of halides; and F. Ephraim calculated that a 10 per cent. expansion occurs during the formation of the trichloride. I. I. Saslowsky studied the contraction during the formation of the halide from its elements. K. M. Stakhorsky studied the mol. association of the liquid. E. H. Amagat found the **compressibility** coeff. of the liquid at 10·1° to be $0{\cdot}0_4 72$ between 1 and 500 atm. press.; $0{\cdot}0_4 54$ between 500 and 100 atm.; $0{\cdot}0_4 45$ between 1000 and 1500 atm.; $0{\cdot}0_4 38$ between 1500 and 2000 atm.; $0{\cdot}0_4 33$ between 2000 and 2500 atm.; and $0{\cdot}0_4 29$ between 2500 and 3000 atm. P. W. Bridgman found the following relations between the press., p kgrm. per sq. cm., and the vol. of the liquid:

p . .	1	500	1000	2500	5000	8000	10,000	12,000
v 20° .	1·0234	0·9862	0·9593	0·9057	0·8521	0·8133	0·7929	0·7763
40° .	1·0485	1·0040	0·9739	0·9159	0·8600	0·8196	0·7989	0·7818

T. W. Richards represented the *vp*-curve of a millilitre of the trichloride up to 12,000 atm. by $p+6200(v-0{\cdot}67)=2050$. W. Ramsay and J. Shields found the **surface tension** of the liquid to be 28·71 dynes per cm. at 16·4°, and 24·91 dynes per cm. at 46·2° ; and the values for the **specific cohesion** are respectively $a^2=3{\cdot}49$ and $a^2=3{\cdot}32$ sq. mm. ; and the mol. **surface energy** at 16·4° is 562·3 ergs and at 46·2°, 499·8 ergs. P. Walden gave 0·00414 for the temp. coeff. of the surface tension, and for the sp. cohesion at $\theta°$, $a^2=4{\cdot}05(1-0{\cdot}000338\theta)$. F. M. Jäger found the sp. gr. referred to water at 4°, the specific cohesion a^2 in sq. mm., the surface tension, σ, in dynes per cm., and the mol. surface energy, μ, in ergs per sq. cm. :

	−70°	−20·5°	0°	35·2°	64·8°	75·1°
Sp. gr. . .	1·744	1·653	1·613	1·547	1·492	1·475
a^2 . . .	4·37	3·90	3·70	3·40	3·13	3·03
σ . . .	37·4	31·6	29·3	25·8	22·9	21·9
μ . . .	687·4	601·9	567·3	513·6	467·0	450·1

R. Lorenz and W. Herz studied some relations of the surface tensions of the family of halides. N. de Kolossowsky studied the relation between the capillary constants and the heat of vaporization.

The mean coeff. of **thermal expansion** of the gas given by L. Troost and P. Hautefeuille is 0·00489 at 100°–125° ; and 0·00417 at 125°–180°. J. I. Pierre gave 0·001154 for the coeff. of cubical expansion of the liquid between —36° and 75° ; T. E. Thorpe, 0·001211 between 0° and 75° ; and P. Walden, 0·00117 between 0° and 60°. I. I. Saslowsky studied the relation between the coeff. of expansion and the chemical structure. H. V. Regnault found 0·1346 to 0·1347 for the **specific heat** of the vapour at constant press. between 111° and 246°. The **vapour pressure,** p mm., of the liquid found by H. V. Regnault is :

	−20°	−10°	0°	10°	20°	30°	40°	50°
p . . .	37·98	62·88	100·55	155·65	233·78	341·39	485·63	674·33

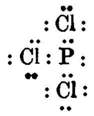
The results were represented by $\log p=4{\cdot}7479108-3{\cdot}1684558a^{\theta}$, where $\log a=\bar{1}{\cdot}9968895$; and C. Antoine gave $\log p=1{\cdot}2112\{5{\cdot}6885-1000(\theta+228)^{-1}\}$. P. de Mondesir also made observations on this subject. F. M. Raoult measured the lowering of the vap. press. by organic substances dissolved in the trichloride. The **boiling point** found by J. B. A. Dumas was between 76° and 78° ; H. V. Regnault gave 73·8° at 760° ; H. L. Buff, 76° ; P. Köchlin and K. Heumann, 75° ; B. Pawlewsky, 75·5° ; H. Kopp, and L. Troost and P. Hautefeuille, 78° ; A. Haagen, 76·7° at 745·9 mm. ; J. I. Pierre, 78·3° at 751·5 mm. ; T. Andrews, 78·5° at 767 mm. ; F. M. Jäger, 75° at 749 mm. ; P. Walden, 76°–76·3° at 763 ; and T. E. Thorpe, 75·95° at 760 mm., and 76·25° at 768 mm. N. de Kolossowsky gave 4·36 to 4·67 for the **ebulliscopic constant.** H. V. Regnault gave 67·24 Cals. for the **heat of vaporization** per kilogram, and 9·25 Cals. per mol. ; and T. Andrews gave respectively 51·42 Cals. and 7·1 Cals. at 78·5°. J. Natterer found that the liquid does not freeze at —115°, but S. A. von Wroblewsky and K. Olschewsky gave about —111·5° for the **melting point ;** and F. M. Jäger, —90°. G. N. Huntly found that a mol of phosphorus trichloride dissolved in 100 mols of phosphoryl chloride lowers the f.p. 0·48°—F. M. Raoult gave 0·63° ; and S. U. Pickering found that with benzene as solvent, the molar depression was 0·6305° to 0·6382°. B. Pawlewsky found the **critical temperature** to be 285·5°, and W. Ramsay and J. Shields, 290·5°. L. Kahlenberg and A. T. Lincoln measured the lowering of the f.p. of soln. of phosphorus trichloride in nitrobenzene. N. de Kolossowsky studied the relation between the coeff. of expansion and the latent heat of vaporization.

B. H. Wilsden studied the energy involved in the electronic shifts during the dissociation of phosphorus trichloride. J. Thomsen found for the **heat of formation** of the liquid trichloride (P,3Cl)=75·3 Cals. ; M. Berthelot and W. Louguinine, 76·6 Cals. ; and J. Ogier, 75·8 Cals. J. Thomsen gave 65·14 Cals. for the **heat of solution** of a mol of the trichloride in 1000 mols of water ; M. Berthelot and W. Longuinine found that one eq. of phosphorus trichloride develops 63·3 Cals.

when treated with about 100 times its weight of water; with a soln. of potassium hydroxide (1 : 50), 132·4 Cals. Observations were also made by P. A. Favre and J. T. Silbermann, H. W. Schröder van der Kolk, and J. Thomlinson.

E. Mascart found the **index of refraction** of phosphorus trichloride vapour to be 1·0001740 for Na-light. F. F. Martins, and J. H. Gladstone and T. P. Dale measured the index of refraction of the liquid trichloride, and A. Stiefelhagen gave for light of wave length $\lambda=263$, 394, and $768\mu\mu$, the index $\mu=1{\cdot}664$, 1·54274, and 1·50340, and $\mu^2=1{\cdot}63317+0{\cdot}59309\lambda^2(\lambda^2-178{\cdot}82^2)^{-1}$. A. Haagen gave for the **refraction equivalent,** 44·3. W. A. Miller said that the colourless liquid absorbs completely the so-called chemical rays of the spectrum. C. R. Crymble measured the absorption spectrum of the trichloride. J. E. Purvis observed no absorption bands in the ultra-violet. H. Davy found the liquid is a non-conductor of electricity; and P. Walden, and A. Voigt and W. Biltz said that at 25° the **electrical conductivity** of the liquid is almost zero—*vide infra,* phosphorus pentachloride. L. Kahlenberg and A. T. Lincoln found the mol. electrical conductivity in ethyl acetoacetate to be $\mu_{1\cdot80}=0{\cdot}026$; and $\mu_{4\cdot48}=0{\cdot}097$; and in nitrobenzene, $\mu_{8\cdot43}=0{\cdot}026$, and $\mu_{16\cdot86}=0{\cdot}042$. W. Finkelstein found the **decomposition voltage** in nitrobenzene soln. to be 0·82 volt. H. Schlundt gave 3·72 for the dielectric constant at 18°; and P. Walden, 4·7 at 22°. A. Bertin found the coefficient of **magnetic polarization** to be 0·51 when that of flint glass is unity.

The analyses of H. Davy, J. J. Berzelius, J. B. A. Dumas, and P. Köchlin and K. Heumann agree with the empirical formula PCl_3; the vap. density determinations of H. V. Regnault, and J. B. A. Dumas agree with the mol. formula PCl_3. This result is also in harmony with the state of the chloride in benzene and phosphoryl chloride soln. determined by G. N. Huntly, and S. U. Pickering; and W. Ramsay and J. Shields, determinations of the surface energy agree that the mol. wt. of the liquid and gas is the same because the association factor is only 1·02. H. Henstock discussed the electronic structure; and G. W. F. Holroyd gave



$$\begin{array}{rl} & :\ddot{\mathrm{Cl}}: \\ :\ddot{\mathrm{Cl}}: & \ddot{\mathrm{P}}: \\ {}^{\bullet\bullet} & :\underset{\bullet\bullet}{\ddot{\mathrm{Cl}}}: \end{array}$$

The chemical properties of phosphorus trichloride.—H. Davy[4] likened the odour of phosphorus trichloride to that of hydrochloric acid; and he said that the liquid has no action on litmus. P. W. Butjagin found that air with 0·004 mgrm. of the trichloride per litre produced very slight symptoms of a disturbance in 6 hrs.; air with 3 mgrms. per litre caused the death of animals in 3 hrs. As indicated above, A. Besson and A. Fournier showed that when a mixture of **hydrogen** and phosphorus trichloride is subjected to the silent electric discharge, phosphorus dichloride is formed. H. Davy said that the vapour burns in the flame of a candle. A. Michaelis said that at ordinary temp. phosphorus trichloride shows no very marked affinity for **oxygen,** but it does so at a higher temp. According to W. Odling, phosphorus trichloride absorbs oxygen at ordinary temp., and is thereby transformed into the oxychloride; and A. Michaelis said that the oxidation is very incomplete even after boiling for 3 days. W. D. Bancroft and H. B. Weiser found that when a cold surface is placed in a flame fed with phosphorus trichloride, a dull deposit of red phosphorus is formed. I. Remsen said that **ozone** transforms the trichloride into the oxychloride. H. Davy said that the trichloride reacts with **water** with a rise of temp. and the gradual formation of hydrochloric and phosphorous acids: $PCl_3+3H_2O=H_3PO_3+3HCl$. M. Trautz observed no signs of luminescence during the reaction between phosphorus trichloride and hot or cold water. K. Kraut observed that if water insufficient for the complete reaction is added to phosphorus trichloride, some red phosphorus and phosphoric acid may be formed: $5PCl_3+12H_2O=3H_3PO_4+15HCl+2P$; and he thought that the phosphorous acid first formed reacts with the phosphorus trichloride: $PCl_3+4H_3PO_3$

$=3H_3PO_4+3HCl+2P$; whereas A. Geuther represents the reaction: $4H_3PO_3=3H_3PO_4+PH_3$; and $PCl_3+PH_3=2P+3HCl$. A. Geuther said that the separation of phosphorus occurs only with impure trichloride and that the alleged phosphorus is really arsenic derived from the arsenic chloride contamination. A. Besson found that when a small proportion of water is used, some phosphoryl monochloride may be formed. The reaction was also studied by A. Michaelis; and G. Carrara and I. Zoppelari found that the progress of decomposition in the heterogeneous system: water-phosphorus trichloride can be represented by $(1/aSt)\log a/(a-x)=k$, where S represents the surface area of the liquids in contact; a, the quantity of decomposable liquid; x, the quantity of liquid decomposed at the time t; and k is the velocity constant 0·000297. According to A. D. Mitchell, when phosphorus trichloride is hydrolyzed by water the soln. produced has much stronger reducing properties when first formed than has a normally produced soln. of phosphorous acid; its acidity is 98 per cent. of the theoretical at first, and gradually increases during ½ hr. to the maximum, probably owing to the intermediate formation and gradual decomposition of an oxychloride. The duration of increased reducing power is greater than can be attributed to the formation of the oxychloride, and is most probably due to the presence of the active tautomeric form of phosphorous acid, $P(OH)_3$, which is slowly converted into the normal form $HPO(OH)_2$. N. V. Sidgwick discussed the nature of the first attack by water on the trichloride.

H. Moissan said that phosphorus trichloride reacts with **fluorine** with incandescence, forming chlorine and the pentafluoride. It was shown by F. Donny and J. Mareska, J. B. A. Dumas, J. Personne, and A. Schrötter, that **chlorine** converts the trichloride into the pentachloride (*q.v.*). H. Wichelhaus said that **bromine** forms a compound with the trichloride only in the cold; A. Michaelis, and A. Prinvault said that reaction occurs at ordinary and at elevated temp. A. L. Stern found a progressive substitution and addition of bromine when the proportion of bromine and the temp. are varied. C. A. Wurtz said that **iodine** does not react with the trichloride; and J. H. Gladstone, that iodine dissolves in the liquid without forming a compound. H. Ritter said that a soln. of iodine in acetic acid forms phosphorus diiodide. C. G. Moot showed that if the soln. of iodine in phosphorus trichloride is allowed to stand for some time, brown trichlorodiiodide is formed. J. H. Gladstone observed that liquid bromine sinks in liquid phosphorus trichloride without mixing, but if a little iodine is added, a vigorous reaction accompanied by the development of heat sets in: $PCl_3+I+5Br=PBr_5+ICl_3$. E. Baudrimont said that the trichloride reacts with **iodine pentabromide,** forming phosphorus triiodide and pentabromide. A. Besson obtained the tribromide by the action of **hydrogen bromide** on the trichloride, although some chlorobromide may be formed. P. Hautefeuille said that when the trichloride is heated with **hydrogen iodide,** hydrogen chloride and phosphorus triiodide are produced. H. L. Snape found that the trichloride is not attacked by **potassium bromide** if oxygen and moisture be excluded, while **potassium iodide** furnishes phosphorus iodide. E. Dervin said that there is a vigorous reaction with **potassium chlorate:** $3PCl_3+KClO_3=3POCl_3+KCl$.

J. H. Gladstone said that **sulphur** does not react with phosphorus trichloride at the b.p., about 78°, but at 140°, L. Henry found that thiophosphoryl chloride is formed. U. Antony and G. Magri showed that phosphorus trichloride dissolves in liquid **hydrogen sulphide,** forming a colourless liquid; there is a rise of temp. during the dissolution, 100 c.c. of the liquid sulphide dissolving 0·11 grm. of the trichloride, and the soln. is an electrical conductor. G. S. Sérullas, and E. Baudrimont found that gaseous hydrogen sulphide reacts with the liquid, forming phosphorus sulphide and hydrogen chloride. W. Biltz and E. Keunecke found that dry, liquid hydrogen sulphide dissolves phosphorus trichloride without the vap. press. of the soln. curve showing any discontinuity; and G. N. Gaum and J. A. Wilkinson found that the soln. are electrical conductors. According to A. Michaelis, **sulphur dioxide** mixes with phosphorus trichloride, but there is no chemical action, even at 140°; when passed through a red-hot tube, the mixed vapours form sulphur, and phosphoryl and thiophosphoryl chlorides. H. E. Armstrong, and A. Michaelis observed that the trichloride reacts vigorously with **sulphur trioxide,** forming sulphur dioxide and phosphoryl chloride—the former observed that a by-product, possibly phosphorus dioxymonochloride, is formed. H. Rose also studied this reaction. A. Michaelis found that conc. **sulphuric acid** on standing in contact with the trichloride reacts: $2PCl_3+3H_2SO_4=2SO_2+P_2O_5+5HCl+HSO_3Cl$; but A. Geuther symbolized the reaction: $PCl_3+2H_2SO_4=SO_2+2HCl+HPO_3+HSO_3Cl$. A. Michaelis found that when the trichloride is heated at 160° with **sulphur monochloride,** the reaction is symbolized: $3PCl_3+S_2Cl_2=PCl_5+2PSCl_3$; and with **thionyl chloride:** $3PCl_3+SOCl_2=PCl_5+POCl_3+PSCl_3$; he also found that in the cold **chlorosulphonic acid** produces sulphur dioxide and hydrogen chloride, a reaction symbolized by A. Geuther: $PCl_3+HSO_3Cl=POCl_3+SO_2+HCl$. A. Michaelis found that **pyrosulphuryl chloride** reacts in the cold, forming phosphorus pentachloride, phosphoryl chloride, and sulphur dioxide. A. Michaelis said that some heat is developed when **selenium dioxide** is mixed in the cold with phosphorus trichloride, and the mixture becomes red-hot; if heated in a sealed tube at 100°–110°, the reaction is symbolized $SeO_2+2PCl_3=Se+2POCl_3$; and when **selenyl chloride** is mixed with the trichloride, some heat is developed, and the reaction is symbolized: $3PCl_3+3SeOCl_2=SeCl_4+Se_2Cl_2+3POCl_3$. E. Baudrimont symbolized the reaction with **selenium tetrachloride**: $6PCl_3+7SeCl_4=3(PCl_5)_2SeCl_4+2Se_2Cl_2$. V. Lenher found that **tellurium dioxide** is reduced to tellurium.

E. A. Schneider found that when passed over **magnesium nitride** at a red-heat, a mixture of the vapour of phosphorus trichloride and nitrogen forms no phosphorus nitride. H. Perpérot found that by mixing soln. of ammonia and of phosphorus trichloride in carbon tetrachloride, impure **phosphorus hexamminotrichloride,** $PCl_3.6NH_3$, is formed, and he represented the reactions with the tri-, penta-, or oxychloride as involving the primary reaction: $PCl_n+2nNH_3=PCl_n.2nNH_3$ and $PCl_n.2nNH_3=nNH_4Cl+P(NH_2)_n$. There is a break on the time-decomposition curve at 200°. J. Perzoz also obtained **phosphorus octamminotrichloride,** $PCl_3.8NH_3$. A. Michaelis and A. Geuther found that **nitrogen peroxide** reacts slowly with well-cooled phosphorus trichloride, forming pyrophosphoryl chloride, phosphoryl chloride, phosphorus pentoxide, nitrosyl chloride, nitrogen, and nitric oxide; and J. Perzoz and N. Bloch said that an explosion occurs when the trichloride is brought in contact with **nitrous acid** or with **nitric acid.** H. Davy said that warm phosphorus trichloride dissolves a little phosphorus, and when the soln. is exposed to air, it deposits a film of **phosphorus**; while paper moistened with the soln. takes fire in air as soon as the liquid has evaporated; if the soln. be exposed to air in daylight, hydrated phosphoric acid is deposited; and, according to U. J. J. Leverrier, in sunlight, phosphorus tetritoxide is deposited. J. J. Berzelius said that when the soln. is treated with water it forms hydrochloric and phosphorous acids with the deposition of clear, transparent phosphorus. H. Rose, and R. Mahn found that the trichloride reacts with **phosphine,** forming hydrogen chloride and phosphorus; A. Besson said that hydrogen diphosphide not phosphorus is produced; and P. de Wilde found that purified phosphine reacts only slowly, and that **hydrogen hemiphosphide** vapour reacts producing hydrogen chloride and hydrogen diphosphide, not phosphorus; **phosphonium iodide** reacts with the trichloride, forming hydrogen chloride, phosphine, hydrogen diphosphide, and phosphorus diiodide. A. Michaelis and M. Pitsch represented the reaction with **hypophosphorous** acid: $4H_3PO_2+2PCl_3=P_4O+H_3PO_3+H_3PO_4+6HCl$. A. Geuther gave $3H_3PO_2+PCl_3=2H_3PO_3+2P+3HCl$. T. E. Thorpe and A. E. H. Tutton found that **phosphorous oxide** has scarcely any action on the trichloride at ordinary temp., or at the b.p., but at 180°, $5P_4O_6+5PCl_3=3PCl_5+6P_2O_5+10P$. A. Naquet found that with **phosphorous acid,** phosphorous oxide is formed; and A. Besson represented the reaction with a conc. soln. of phosphorous acid: $2H_3PO_3+2PCl_3=6HCl+P_4O_6$, and $P_4O_6=P_2O+P_2O_5$. When the trichloride is heated with **phosphoric acid** on a water-bath, A. Geuther symbolized the reaction: $3H_3PO_4+PCl_3=3HPO_3+H_3PO_3+3HCl$; followed by a reaction between the trichloride and the phosphorous acid producing metaphosphoric and pyrophosphoric acids. He symbolized the reaction with **pyrophosphoric acid**: $3H_4P_2O_7+PCl_3=6HPO_3+H_3PO_3+3HCl$, along with the formation of some red phosphorus. According to F. Krafft and R. Neumann, **arsenic** and phosphorus trichloride do not react at 320°, but if a little arsenic chloride be present, the reaction is almost quantitative at 200°. J. V. Janowsky symbolized the reaction with **arsine**: $AsH_3+PCl_3=PAs+3HCl$. A. Michaelis found that **arsenic trioxide** is reduced to arsenic at 100°, and at 130°, he symbolized the reaction: $5As_2O_3+6PCl_3=4As+6AsCl_3+3P_2O_5$; but **arsenic pentoxide** does not react with the trichloride at 200°. H. Moissan observed that with **arsenic trifluoride,** some dark brown arsenic is formed. A. W. Cronander obtained a crystalline mass of *arsenic phosphoctochloride,* $AsCl_5.PCl_3$, by dissolving phosphorus pentachloride in arsenic trichloride. E. Beckmann said that **arsenic triiodide** is sparingly soluble in phosphorus trichloride, while P. Walden found the dried **arsenic trihalides** to be all fairly soluble in that menstruum. E. Baudrimont showed that heated **antimony** reacts with phosphorus trichloride, forming antimony trichloride and phosphorus; and F. Krafft and R. Neumann studied the reaction at 200°. R. Mahn said that **stibine** does not react with phosphorus trichloride. A. Michaelis said that the trichloride reacts with **antimony trioxide**, producing red phosphorus and antimony trichloride; and with **antimony pentoxide** the reaction is symbolized: $Sb_2O_5+2PCl_3=2SbCl_3+P_2O_5$. E. Beckmann said that antimony triiodide is sparingly soluble in phosphorus trichloride, but P. Walden said that antimony trihalides are all fairly soluble. H. A. Köhler observed that phosphorus trichloride reacts with **antimony pentachloride,** forming a complex $2SbCl_5+PCl_3=SbCl_3+PCl_5.SbCl_5$. A. Michaelis showed that **bismuth** forms a little phosphorus when heated with phosphorus trichloride; and at 160°, in a sealed tube, **bismuth oxide** reacts with phosphorus trichloride, forming bismuth dichloride and phosphate, and bismuthyl and phosphoryl chlorides. F. E. Brown and J. E. Snyder observed that **vanadium oxytrichloride** is reduced by phosphorus trichloride, forming a precipitate.

G. Gustavson observed no reaction with **boron trioxide** when heated with phosphorus trichloride for 2 weeks at 200°; J. Tarible showed that with **boron tribromide,** a complex *boron phosphohexabromotrichloride,* $2BBr_3.PCl_3$, is formed. Phosphorus trichloride reacts with numerous **organic compounds**—alcohols, acid anhydrides, acids, etc.—forming chlorides. It is an important reagent in many organic syntheses. A. G. Page discussed its use as a catalyst in organic chlorinations. This subject was also discussed by Lassar Cohn. Phosphorus trichloride is used as a reagent for replacing hydroxyl groups by chlorine. It was first employed for this purpose by A. Béchamp in 1856, who found that **acetic acid,** CH_3COOH, could be converted into acetyl chloride, CH_3COCl, by a reaction symbolized: $3CH_3COOH+PCl_3=H_3PO_3+3CH_3COCl$. This principle is applied in determining the number of hydroxyl groups in acids—*e.g.* sulphurous and sulphuric acids. Many of the oxy-halides can be regarded as products obtained by replacing the HO-group in the acid by chloride—*e.g.* $(HO)_4P_2O_3$, pyrophosphoric acid furnishes pyrophosphoryl chloride, $P_2O_3Cl_4$. The action of phosphorus trichloride on the aliphatic **alcohols** was studied by A. Béchamp, and T. Milobendzky and A. Sachnowsky. The first product of the reaction is the normal phosphorous ester which is decomposed by the liberated hydrogen chloride into acid ester and alkyl chloride. J. W. Walker and F. M. G. Johnson represented the reaction with methyl, ethyl, and *n*-propyl alcohols by the typical equation: $PCl_3+3CH_3OH=2CH_3Cl+HCl+P(OH)_2(OCH_3)$. V. Auger found that phosphorus trichloride reacts at −20° with **methyl, ethyl, or propyl iodide** to form alkyl phosphines. B. T. Brooks found that when acetic acid reacts with phosphorus trichloride, in addition to acetyl chloride there are simultaneously formed small quantities of acetyl anhydride and of *acetyl phosphorous acid,* $(CH_3CO.O)P(OH)_2$. P. Carré found that the trichloride reacts with **glycerol**, and with **glycol**; in the former case, phosphorous esters are formed. P. Walden found the trichloride to be a good solvent for numerous organic compounds, but not for many inorganic compounds. R. Mahn said that **silane** was not perceptibly affected by phosphorus trichloride. A. Bertrand obtained with **titanium tetrachloride** the complex *titanium phosphoheptachloride*, $TiCl_4.PCl_3$, in crystals melting at 85·5°. T. Karantassis observed that phosphorus trichloride undergoes double decomposition with **titanium tetraiodide**, but the reverse reaction does not occur even in sealed tubes at 200°. It is concluded that the chlorides of the tervalent metalloids undergo double decomposition with the **iodides of carbon, silicon, titanium, zirconium, thorium, germanium, and hafnium**, but do not react with **stannic chloride.**

H. Davy said that **potassium** burns vigorously in the vapour of phosphorus trichloride, and J. H. Gladstone observed that the trichloride sets fire to potassium. H. Beutler and M. Polanyi observed chemiluminescence in the reaction with **sodium**; and V. C. Vournasos represented the reaction with heated sodium: $PCl_3+6Na=3NaCl+Na_3P$; and in boiling toluene soln., potassium furnishes potassium chloride and phosphide. According to A. Granger, when the vapour of the trichloride is passed over heated **copper**, or when copper is heated with the trichloride, crystalline copper diphosphide is formed; L. Wolf also studied this reaction. According to J. H. Gladstone, the liquid trichloride does not react with **silver**, but after shaking the mixture 2 weeks at 100°, L. Wolf found the reaction: $PCl_3+3Ag=3AgCl+P$ occurred. L. Wolf found that phosphorus trichloride has only a slight action on **magnesium**. W. T. Casselmann, L. Wolf, and B. Reinitzer and H. Goldschmidt found that with **zinc** at 100°, zinc chloride and phosphorus are formed; and G. Denigès said that dry zinc powder does not act on the liquid. L. Wolf represented the reaction which occurs when **mercury** is shaken a long time with phosphorus trichloride as forming mercury and mercurous chloride; and with **aluminium** at 100°, $PCl_3+Al=AlCl_3+P$. J. L. Gay Lussac and L. J. Thénard said that when the trichloride is heated with **iron** filings, ferric chloride and iron phosphide are formed—A. Granger represented the phosphide so produced by Fe_4P_3; and for the corresponding case with **nickel**, Ni_5P_2, and later, Ni_2P; and with **cobalt** at 500°, Co_2P.

A. Michaelis represented the reaction with **copper oxide**, $17CuO+5PCl_3=2Cu_3(PO_4)_2+10CuCl+CuCl_2+POCl_3$; and with mercury oxide he employed an analogous equation. At 160°, **stannic oxide** reacts: $5SnO_2+4PCl_3=4SnCl_2+SnCl_4+2P_2O_5$; and W. T. Casselmann obtained no complex with **stannous chloride**; **lead oxide** does not react at 160°, but at higher temp., $6PbO+2PCl_3=Pb(PO_3)_2+3PbCl_2+2Pb$; and with **lead dioxide**, $4PbO_2+4PCl_3=Pb(PO_3)_2+3PbCl_2+2POCl_3$; A. Michaelis said that phosphorus trichloride reacts with **potassium dichromate**: $30K_2Cr_2O_7+42PCl_3=18KCrO_3Cl+15KPO_3+42CrO_2+27KCl+27POCl_3$; with **chromyl chloride**: $4CrO_2Cl_2+6PCl_3=4CrCl_3+PCl_5+3POCl_3+P_2O_5$; or $6CrO_2Cl_2+9PCl_3=6CrCl_3+7POCl_3+P_2O_5$; H. S. Fry and J. L. Donnelly said that the violence of the reaction can be moderated in soln. of dry carbon tetrachloride when a complex *chromyl phosphoryltetrachloride*, $CrOCl.POCl_3$, is formed. It is decomposed by water. According to A. Michaelis, phosphorus trichloride produces only a superficial green film on **tungsten trioxide** at 200°; and with **molybdenum trioxide**, a superficial blue film; but in a sealed tube at 160°: $MoO_3+PCl_3=MoO_2+POCl_3$, followed by $3MoO_3+2POCl_3=3MoO_2Cl_2+P_2O_5$; **manganese dioxide**, and **ferric oxide** are not attacked. E. Baudrimont found that with **potassium, calcium, or barium sulphide**, at a red-heat, the corresponding chloride and phosphorus sesquisulphide are formed; with **mercuric sulphide**, both mercuric and mercurous chlorides are formed as well as mercury thiophosphide, and if the phosphorus chloride is in excess, phosphorus sesquisulphide is produced. At a red-heat, **antimony trisulphide** forms antimony trichloride and phosphorus sesquisulphide—and may be a red antimony thiophosphide. The action on **lead sulphide** is similar. L. Wolf found **cuprous chloride** furnishes **dicuprous phospho-**

pentachloride, and a similar product is obtained with **cuprous bromide**; no addition product is formed with **silver chloride or bromide.** Phosphorus trichloride was found by H. Moissan to react with **silver fluoride,** forming phosphorus trifluoride. L. Wolf observed the formation of no complex salt between phosphorus trichloride and **mercury chloride or bromide,** but H. Moissan found that the trichloride forms a complex with **zinc fluoride,** and, according to A. Guntz, with **lead fluoride.** L. Lindet obtained complex salts with **aurous chloride** and **aurous bromide,** namely, **aurous phosphotrichlorobromide,** $AuBr.PCl_3$, and **aurous phosphotetrachloride,** $AuCl.PCl_3$. M. Levi-Malvano added phosphorus trichloride to a soln. of **auric chloride** in ether and obtained **auric phosphohexachloride,** $AuCl_3.PCl_3$. P. Schützenberger also obtained with **platinous chloride,** the complex **platinous phosphopentachloride,** $PtCl_2.PCl_3$; and P. Schützenberger and M. Fontaine, **platinous diphosphoroctochloride,** $PtCl_2.2PCl_3$; G. Geisenheimer, and M. F. Schurigin, **iridium triphosphododecachloride,** $Ir(PCl_3)_3Cl_3$; and G. Geisenheimer **iridium triphosphopentadecachloride,** IrP_3Cl_{15}, but M. F. Schurigin could not make this. E. Fink obtained **palladous phosphopentachloride,** $PdCl_2.PCl_3$, and **palladous phosphoctochloride,** $PdCl_2.2PCl_3$; and M. F. Schurigen obtained **ruthenic pentaphosphoenneadecachloride,** $Ru_2(PCl_3)_5Cl_4$. M. F. Schurigen represented the constitution of these products by the co-ordination formulæ with phosphorus trichloride taking the place of ammonia in the ammines.

P. Biginelli[5] observed that phosphine unites with mercuric chloride to form a yellow mass; and P. Lemoult observed the formation of an unstable intermediate product when phosphine acts on an aq. soln. of mercuric chloride and potassium chloride. If the gas be confined over the liquid and suddenly shaken, the resulting yellow precipitate can be dried in vacuo over sulphuric acid. Its composition corresponds with **phosphorus triochloromercuriate,** $P(HgCl)_3$, or $HgCl_2.PHg_2Cl$. H. Rose obtained a product approximating to a *hemitrihydrate* by the action of phosphine on an aq. or alcoholic soln. of mercuric chloride. A. Partheil and A. van Haaren worked with an alcoholic soln. and said that the phosphine should be diluted with an inert gas. D. Vitali obtained a similar substance. The yellow product is decomposed by heat; by boiling water; conc. alkali-lye; hydrogen sulphide; and by dil. nitric acid. For analogous reactions with mercuric bromide and iodide, *vide infra.*

§ 32. Phosphorus Pentachloride or Phosphoric Chloride

As previously indicated, this compound is formed as a white solid when phosphorus is burnt in contact with an excess of chlorine. It was first made by H. Davy[1] in this way in 1810, but its nature was not definitely established until 1816, when P. L. Dulong's analysis, translated into modern symbols, showed it to possess the ultimate composition PCl_5. It was also analyzed by J. J. Berzelius, W. T. Casselmann, and E. B. R. Prideaux. The vapour density presents an anomaly. The theoretical value, according to Avogadro's law, is 7·22, the value observed by A. Cahours is 5·08 at 182°, and at temp. exceeding 300°, it has the constant value 3·65, which is about half what was anticipated. In the struggle of Avogadro's hypothesis for recognition (**1.** 5, 7), the advocates of the atomic theory attributed the anomaly to the dissociation of the molecule with rise of temp., $PCl_5 \rightleftharpoons PCl_3 + Cl_2$. This stimulated quite a number of observations on the subject. The general results show that phosphorus pentachloride is only partially dissociated at the lower temp. of observation employed by A. Cahours, and that dissociation is complete above 300°. When due allowance is made for this dissociation, the vapour density agrees with the formula PCl_5. This formula also agrees with G. Oddo and E. Serra's determination of the mol. wt. from the effect of the pentachloride on the b.p. of carbon tetrachloride. Historically, phosphorus pentachloride played a part in the development of the concept of valency--*vide supra*, the valency of phosphorus—and in the idea of the so-called molecular compounds.

Phosphorus pentachloride is made by the action of an excess of chlorine on phosphorus, or by the action of dry chlorine on phosphorus trichloride. Moisture should be rigorously excluded so that the two components should be thoroughly dried. Since phosphorus pentachloride is a very unpleasant substance to manipulate in air, owing to the fact that it rapidly absorbs moisture, forming hydrochloric and phosphoric acids: $PCl_5 + 4H_2O = 5HCl + H_3PO_4$, H. Davy, E. Baudrimont, etc., found it best to make the compound in the bottle in which it was to be preserved. Fit the bottle with a three-hole stopper—one hole for the tube bringing in dry chlorine, one for the exit of the chlorine, and the third for a tap funnel by means of which phosphorus trichloride can be run into the chlorine drop by drop. Much heat is evolved during the reaction, so that it is well to keep the vessel well covered by a freezing mixture. H. A. Taylor described a modification of the process. W. Biltz and K. Jeep studied the thermal diagram of mixtures of phosphorus trichloride and chlorine, and the incomplete results, Fig. 49, are not incompatible with the assumption that a still higher polychloride exists. H. Müller obtained the pentachloride in crystals by passing chlorine into a soln. of phosphorus trichloride in carbon disulphide, when most of the pentachloride is precipitated as fast as it is formed. A. Michaelis made the compound by heating phosphorous chloride with sulphur monochloride: $3PCl_3+S_2Cl_2=PCl_5+2PSCl_3$, similarly with thionyl chloride; the presence of a trace of iodine acts as a stimulant on the reaction: $3PCl_3+SOCl_2=PCl_5+POCl_3+PSCl_3$, and an 88 per cent. yield can be obtained. H. Davy, and T. Thomson observed that the pentachloride is produced when chlorine is passed into phosphine; and R. Mahn obtained it by the action of phosphine on antimony pentachloride: $PH_3+4SbCl_5=4SbCl_3+3HCl+PCl_5$; and A. J. Balard, by the action of chlorine on the pentabromide. W. T. Casselmann said that phosphorus trichloride slowly decomposes on keeping, forming phosphorus and its pentachloride, but this observation needs verification. A. Michaelis and M. Pitsch obtained the pentachloride by the action of an excess of chlorine on phosphorus tetritoxide; A. Besson, on the hemioxide in the presence of carbon tetrachloride; T. E. Thorpe and A. E. H. Tutton, on phosphorous oxide; and H. Quantin, by heating ferric phosphate, or calcium phosphate, in the vapour of carbon tetrachloride. C. Poulenc heated phosphorus trifluodichloride to 200°–250°, and exposed it to the action of electric sparks: $5PF_3Cl_2=3PF_5+2PCl_5$.

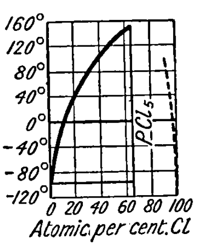

FIG. 49.—Thermal Diagram of the System: PCl_3–Cl_2.

Phosphorus pentachloride at ordinary temp. is a white, crystalline powder which fumes in air. According to P. Kremers, and A. Michaelis, it forms a mass of columnar crystals when cooled from the molten mass; and when obtained from a mixture of thionyl chloride, or, according to B. Corenwinder, by the action of chlorine on a sat. soln. of phosphorus in carbon disulphide, it appears in rhombic plates which, according to A. E. Nordenskjöld, belong to the tetragonal system, and have the axial ratio $a:c=1:0{\cdot}5672$. E. B. R. Prideaux found the sp. gr. of the solid at 160° to be 1·601, the sp. vol., 0·629; and the mol. vol., 128·9. The at. vol. of the contained phosphorus is 15·10. The thermal expansion represented by the vol., v, at $\theta°$, between 160° and 190° is $v=1+0{\cdot}00107\theta$. E. Mitscherlich[2] found the vap. density to be 4·85 (air unity) at 185°; and A. Cahours gave for the vap. densities at different temp.,

	182°	200°	230°	250°	274°	300°	327°	336°
Vap. density .	5·078	4·851	4·302	3·991	3·840	3·654	3·656	3·656
Dissociation .	41·7	48·5	67·4	80	87·5	96·2	97·3	97·3 per cent.

so that above 300°, the vap. density corresponds with 3·61, that of a mixture of equal vols. of phosphorus trichloride and chlorine. H. St. C. Deville noticed that the vapour has a yellowish-green colour at the higher temp This is due to the presence of free chlorine; the colour becomes darker the higher the temp. Paper moistened with starch and potassium iodide soln. also shows a blue coloration, characteristic of that produced by chlorine, when immersed in the vapour of phosphorus pentachloride at 157°–158°. A. Naumann calculated the percentage dissociation of the vapour, and his results are indicated above. A. Smith and R. H. Lombard obtained the following values for the vapour density:

	90°	100°	120°	140°	160°
Grains per c.c. .	$0{\cdot}0_3197$	$0{\cdot}0_3332$	$0{\cdot}0_3929$	$0{\cdot}0_22286$	$0{\cdot}0_24933$
Mols. per litre .	$0{\cdot}0_3945$	0·00159	0·00446	0·01096	0·02368

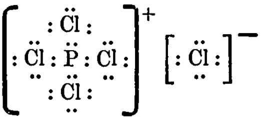
The vapour density at 90° is rather greater than the value required for the undissociated vapour; hence it is inferred that in the vicinity of 100°, some mols. of the vapour are associated into complexes. Above 110°, dissociation is evident. The dissociation of the pentachloride will be represented by the equation: $PCl_5 \rightleftharpoons PCl_3 + Cl_2$. If C_{PCl_5}, C_{PCl_3}, and C_{Cl_2} respectively denote the conc. of phosphorus pentachloride, phosphorus trichloride, and of chlorine, then, according to the mass law, for equilibrium: $kC_{PCl_5} = k'C_{PCl_3}C_{Cl_2}$. Suppose that 1 grm. of phosphorus pentachloride be heated in a closed vessel of vol. v. Let x represent the fraction dissociated at any given temp., then there will be C_{PCl_5}, or $(1-x)/v$ mols. of the pentachloride per unit vol.; C_{PCl_3}, or x/v mols. of the trichloride; and C_{Cl_2}, or x/v mols. of chlorine. Hence for equilibrium, the preceding equation reduces to $K = k/k' = x^2/(1-x)v$. It follows that by increasing the conc. of one of the products of the reaction, the dissociation of the pentachloride will be restrained. C. A. Wurtz confirmed this by showing that in the presence of an excess of the trichloride or chlorine the vap. density is near that required for the undissociated pentoxide. R. Wegscheider showed that in C. A. Wurtz's experiments the dissociation amounted to only 3–10 per cent. The reaction has been also studied by H. Wichelhaus, L. Troost and P. Hautefeuille, H. Debray, A. Horstmann, J. W. Gibbs, O. Brill, S. Dushman, R. Wegscheider, P. Blackman, C. Holland, and A. Smith and R. P. Calvert. A. Smith and R. H. Lombard gave for the dissociation press., p, of phosphorus pentachloride:

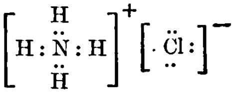
	90°	100°	110°	120°	130°	140°	150°	160°
p . . .	18	35	67	117	191	294	445	670 mm.

They represented the results by $\log p = -6724 \cdot 22T^{-1} - 19 \cdot 1978 \log T + 68 \cdot 9701$ for press. up to 160°. This result enables the mol. heat of vaporization to be calculated:

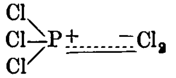
	90°	100°	110°	120°	140°	150°	160°
Heat of vaporization . .	14·2	15·6	16·6	16·9	15·6	14·9	14·9 Cals.

W. T. Casselmann[3] said that phosphorus pentachloride sublimes without melting when heated in air, but a very slight increase of press. suffices to melt it; volatilization occurs as low as 100°, and it sublimes rapidly at 160°. A. Naumann said that the b.p. is 160°–165°. E. B. R. Prideaux found that a thermometer placed in the vapour of phosphorus pentachloride subliming freely, and condensing on the bulb, remains steady at 160°. When the liquid pentachloride is slowly cooled, it begins to solidify at 162°. S. U. Pickering measured the lowering of the f.p. of benzene by phosphorus pentachloride. C. Feliciani found that the vapour of the pentachloride at 100 mm. press. has a thermal conductivity of 0·000165 at 148°, and 0·000234 at 291°. There are maxima, 0·00032 and 0·00033, respectively, at 230° and 270°, with a minimum of 0·000276 at 248°. M. Berthelot gave for the heat of formation (P,5Cl)=107·8 Cals.; J. Thomsen, (P,5Cl)=104·99 Cals., and $(PCl_3,2Cl)$=29·69 Cals. The heat of decomposition of phosphorus pentachloride by water was found by J. Thomsen to be 123·404 Cals.; J. J. B. Abria, 102·368 Cals.; T. Andrews, 109·504 Cals.; and P. A. Favre and J. T. Silbermann, 100·373 Cals. M. Berthelot and W. Longuinine found that one eq. of phosphorus pentachloride reacts with water evolving 118·9 Cals., and with a soln. of potassium hydroxide (1 : 50) evolving 220·1 Cals. The subject was discussed by H. W. Schröder van der Kolk, and J. Thomlinson. C. R. Crymble measured the absorption spectrum of the pentachloride. H. Davy, H. L. Buff, W. Hampe, and A. Voigt and W. Biltz said that this chloride is a non-conductor of electricity. Phosphorus pentachloride behaves like an electrolyte in a suitable solvent—*vide infra*, phosphorus pentabromide. A sat. soln. of phosphorus pentachloride in nitrobenzene was shown by G. W. F. Holroyd to be a conductor, and the introduction of phosphorus trichloride, and of hydrogen chloride reduced the conductivity; a soln. of the pentachloride in ethylene dibromide, benzene, or phosphorus trichloride passed no current. H. Henstock, and S. Sugden discussed the electronic structure; and in accord with the electrolytic character of the pentachloride, G. W. F. Holroyd represented the electronic structure, in a manner analogous to that of ammonium chloride:





According to T. M. Lowry, it is a general rule that if one atom shares two electrons with another, but contributes both electrons to the common stock instead of only one, it acquires a positive charge, whilst its neighbour (which has acquired a half-share in two electrons not originally belonging to it) becomes negatively charged. E. B. R. Prideaux added that regarding the PCl_5 mol. in this manner we see that the pair of chlorine atoms are both united to the phosphorus by a single duplet, and thus completely take the place of an oxygen or sulphur atom, and may be replaced by these but not by OH-groups. The fifth phosphorus valency is an electrovalency, but is not quite the same as an ordinary electrovalency: no electron has passed across and there is no ionization possible, except by passing into the tautomeric form of the NH_4Cl-type. That this mode of union may be a strong one is shown by the fact that PF_5 does not behave as a fluorinating agent. In the case of all halogen compounds which show that maximum valency of the element, halogen atoms equal in number to the hydrogen (or alkyl) valency in each case and replaceable by OH are united in a different manner from the remaining halogen atoms which are replaceable by oxygen or sulphur, or are left free in the lower valent compounds. This gives for phosphorus pentachloride:



explaining the easy detachment, by gaseous dissociation, of the two chlorine atoms.

The chemical properties of phosphorus pentachloride.—There are two important characteristics of the chemical reactions of phosphorus pentachloride: (i) The facility with which chlorine is given up by the scission of the molecule; this shows itself by its acting as an energetic chlorinating agent; and (ii) The tendency of phosphorus pentachloride to unite additively with other chlorides to form complex compounds. E. Baudrimont[4] found that a mixture of the pentachloride with **hydrogen** when passed through a red-hot tube, furnished some phosphorus, phosphine, hydrogen chloride, and phosphorus trichloride. H. Davy said that the pentachloride burns when placed in the flame of a candle; and when the vapour is mixed with **oxygen** and passed through a red-hot tube, phosphoric oxide and chlorine are formed, and, added E. Baudrimont, some phosphoryl chloride is produced at the same time. J. A. Wanklyn and A. Robinson found that the vapour at 300° begins to oxidize in **air.** According to H. Davy, phosphorus pentachloride reacts with **water,** forming phosphoric and hydrochloric acids: $PCl_5+4H_2O=H_3PO_4+5HCl$; but with steam, C. A. Wurtz observed the formation of phosphoryl chloride: $H_2O+PCl_5=POCl_3+2HCl$. G. Oddo assumed that when a mixture of phosphorus pentachloride with varying quantities of water is heated in a reflux apparatus, there is evidence of a step-by-step formation of the products: (i) $Cl_4P.O.PCl_4$; (ii) $Cl_3P{=}O_2{=}PCl_3$; (iii) $Cl_2P{\equiv}O_3{=}PCl_2$; (iv) $(PO_2Cl)_2$; and (v) P_2O_5. The first and penultimate products have not been isolated from the products of the reaction. With the mixture $2PCl_5+H_2O$, half of the pentachloride is converted into oxychloride, the rest being unchanged; the mixture $2PCl_5+2H_2O$ yields the theoretical amount of oxychloride; the mixture $2PCl_5+4H_2O$, or $(POCl_3)_2+H_2O$, gives mainly oxychloride accompanied by a little pyrophosphoryl chloride, $P_2O_3Cl_4$, and phosphoric oxide; and with the proportions $2PCl_5+4H_2O$, or $(POCl_3)_2+3H_2O$, the same products as in the previous case are obtained, the amount of oxychloride being considerably diminished, and that of phosphoric oxide correspondingly increased. M. Trautz observed no luminescence when phosphorus pentachloride reacts with cold or warm water.

H. Moissan found that when the pentachloride is treated with **fluorine,** the whole mass becomes incandescent, and the pentafluoride is formed; **chlorine** and **bromine** have no action; and W. Biltz and E. Meinecke observed that the pentachloride is insoluble in liquid chlorine; and K. H. Butler and D. McIntosh, that the pentachloride has no action on the b.p. of liquid chlorine. According to E. Baudrimont, **iodine** reduces a part of the pentachloride and forms an addition product, phosphorus iodohexachloride, $PCl_5.ICl$, thus: $3PCl_5+I_2=PCl_3+2PCl_5(ICl)$. G. Gore found that the pentachloride is vigorously decomposed by dry **hydrogen fluoride** at —18° to —29°, forming a white powder; and the pentachloride dissolves in liquid **hydrogen chloride,** forming a colourless soln. J. H. Gladstone said that when heated with **hydrogen bromide** there is no reaction; but with **hydrogen iodide,** C. A. Wurtz observed the formation of phosphorus trichloride, hydrogen chloride, and iodine. W. Spring said that when **chlorine trioxide** is passed over phosphorus pentachloride, there is often a vigorous explosion, chlorine monoxide being formed. R. Weber said that **iodic acid** decomposes the pentachloride at ordinary temp. H. Schiff observed that with **potassium chlorate,** phosphoryl chloride is formed.

J. H. Gladstone, and E. Baudrimont found that when phosphorus pentachloride and **sulphur** are fused together, thiophosphoryl chloride is formed. H. Goldschmidt obtained sulphur monochloride by the reaction: $2S+PCl_5=PCl_3+S_2Cl_2$; and O. Ruff found a soln. of phosphorus pentachloride in phosphoryl chloride reacts with sulphur in the presence of iodine forming sulphur monochloride. G. S. Sérullas, and E. Baudrimont represented the reaction with dry **hydrogen sulphide:** $PCl_5+H_2S=2HCl+PSCl_3$; while if a mixture of the two be passed through a red-hot tube, hydrogen chloride and phosphorus pentasulphide are formed. W. Biltz and H. Keunecke found that thiohydrolysis occurs when liquid hydrogen trisulphide is brought in contact with phosphorus pentachloride. H. Schiff represented the reaction which occurs when the pentachloride is warmed with dry **sulphur dioxide** by $PCl_5+SO_2=POCl_3+SOCl_2$; P. Kremers, and J. Persoz and N. Bloch seem to have thought that the product was a chemical individual—the former called it *schwefligsaures Phosphorchlorid,* and the latter *chlorophosphate biacidsulphurique.* A. Michaelis, and K. Heumann and P. Köchlin represented the reaction with dry **sulphur trioxide:** $PCl_5+2SO_3=S_2O_5Cl_2+POCl_3$; the reaction is slow, and requires the application of heat; if the phosphorus pentachloride is in excess, the pyrosulphuryl chloride is decomposed $S_2O_5Cl_2+PCl_5=POCl_3+2Cl_2+2SO_2$, and no thionyl chloride is formed. The reaction was examined by A. W. Williamson, and H. Schiff. A. Michaelis represented the reaction with conc. **sulphuric acid:** $3H_2SO_4+PCl_5=3SO_2(OH)Cl+HPO_3+2HCl$; and the chlorosulphonic acid reacts: $2SO_2(OH)Cl+PCl_5=S_2O_5Cl_2+2HCl+POCl_3$. S. Williams represented the reaction: $PCl_5+H_2SO_4=SO_2(OH)Cl+POCl_3+HCl$, and $2PCl_5+H_2SO_4=SO_2Cl_2+2POCl_3+2HCl$; but A. Michaelis said that no sulphuryl chloride is formed, and F. Baumstark, no phosphoryl chloride, and he represented the reaction with the fuming acid by $4H_2SO_4+PCl_5=4SO_2(OH)Cl+HCl+H_3PO_4$. S. Williams added that the phosphoryl chloride reacts with the sulphuric acid: $2H_2SO_4+POCl_3=2SO_2(OH)Cl+HPO_3+HCl$. The reaction with **chlorosulphonic acid** is indicated above, and with a smaller proportion of acid, A. Michaelis represented the reaction: $2SO_2(OH)Cl+PCl_5=S_2O_5Cl_2+2HCl+POCl_3$. He also found that **sulphuryl chloride** is slowly decomposed into thionyl and phosphoryl chlorides, and chlorine; H. E. Armstrong, and A. Michaelis, that **pyrosulphuryl chloride,** sulphur dioxide, phosphoryl chloride, and chlorine are formed, while A. Geuther represented the reaction: $S_2O_5Cl_2+PCl_5=2SO_2+2Cl_2+POCl_3$, and $PCl_5+SO_2=POCl_3+SOCl_2$. A. Michaelis and O. Schumann found that with **nitroxylsulphonic acid,** the reaction can be symbolized: $SO_2(NO_2)OH$

$+PCl_5=SO_2(OH)Cl+NOCl+POCl_3$. F. Ephraim and M. Gurewitsch found that **amidosulphonic acid** gives amidosulphuryl, phosphoryl, and hydrogen chlorides; and they also reported the formation of the complex $NH_2.SO_2Cl.PCl_3$—*phosphorus amidosulphuryltetrachloride.* W. Spring examined the action of the pentachloride on **thiosulphates**; and K. Kraut found that with thiosulphates it forms thionyl chloride. L. Carius said that **calcium sulphite** is decomposed by phosphorus pentachloride; and K. Kraut found that with **sodium thiosulphate,** thionyl chloride is formed. According to C. Pape, and J. Y. Buchanan, **lead thiosulphate** is decomposed when heated in the vapour of phosphorus pentachloride, and C. W. Blomstrand represented the reaction: $PbS_2O_3+2PCl_5=PbCl_2+POCl_3+PSCl_3+SO_2Cl_2$. E. Baudrimont found that when the pentachloride is heated with **selenium,** the reaction is: $PCl_5+2Se=PCl_3+Se_2Cl_2$. According to A. Michaelis, **selenium dioxide** reacts: $3SeO_2+3PCl_5=3SeOCl_2+3POCl_3$, and the products then interact: $3SeOCl_2+2POCl_3=3SeCl_4+P_2O_5$; E. Baudrimont said a yellow product is formed with **selenium monochloride** at ordinary temp., and this becomes red if heat be employed, but no selenophosphorus chloride is formed. R. Metzner obtained *tellurium phosphotridecachloride,* $2TeCl_4.PCl_5$, by heating **tellurium tetrachloride** and phosphorus pentachloride in a sealed tube at 220°. R. Weber found that **lead selenide** forms lead chloride and a red liquid which gives selenium and hydrogen selenide with water. E. Baudrimont reported that lead selenide at a red-heat forms lead chloride, phosphorus trichloride, and selenium tetrachloride, while **antimony triselenide** yields phosphorus and antimony trichlorides, and selenium monochloride.

H. Davy said that phosphorus pentachloride forms a definite compound with **ammonia**; and H. Rose observed that ammonia is slowly absorbed by the well-cooled pentachloride—*vide* phosphorus. The complex phosphorus chloronitrites, produced by the action of ammonia on the pentachloride, were examined by J. von Liebig and F. Wöhler, J. H. Gladstone, J. H. Gladstone and J. D. Holmes, A. Laurent, H. Wichelhaus, H. N. Stokes, J. Persoz, etc.—*vide* **8.** 49, 73. If ammonia be passed into a soln. of phosphorus pentachloride in carbon tetrachloride, A. Besson found that **phosphorus octamminopentachloride,** $PCl_5.8NH_3$, is formed as a white crystalline mass, which, at about 175°, decomposes into a chloronitrite. H. Perpérot found that when soln. of ammonia and of phosphorus pentachloride in carbon tetrachloride are mixed, impure **phosphorus decamminopentachloride,** $PCl_5.10NH_3$, is formed—*vide supra,* phosphorus trichloride. There is a break in the time-decomposition curve at 310° in agreement with that for ammonium chloride. Hence it is assumed that the decomposition product is a mixture of ammonium chloride and phosphorus pentamide. H. N. Stokes also found that the chloronitrites are produced by the action of the pentachloride on **ammonium chloride.** W. P. Winter observed that phosphorus pentachloride and **sodium amide** react vigorously when warmed, ammonium and sodium chlorides are sublimed, and a compound—possibly PO(NH)(OH) or OP≡NO—is formed. R. Müller found that the pentachloride reacts with **nitrogen peroxide,** forming nitrosyl and phosphoryl chlorides and chlorine. According to J. Persoz and N. Bloch, both **nitrous and nitric acids** react with the pentachloride, forming phosphoric acid, nitrogen, chlorine, and an oxygen compound; while H. Schiff obtained with nitric acid, hydrogen chloride, phosphoryl chloride, and a blood-red liquid. R. Weber decomposed **silver nitrate** by phosphorus pentachloride; and A. Naquet observed that with **potassium nitrate,** nitrosyl and phosphoryl chlorides are formed. J. H. Gladstone said that **phosphorus** has no appreciable action in the cold, but when heated it violently reduces the pentachloride to the trichloride. According to H. Rose, a small proportion of **phosphine** reacts: $3PCl_5+PH_3=3HCl+4PCl_3$; and with phosphine in excess, $3PCl_5+5PH_3=15HCl+8P$. The reaction was also studied by R. Mahn. T. E. Thorpe and A. E. H. Tutton observed that with **phosphorous oxide** there is a lively reaction, and phosphory and phosphorous chlorides are formed; M. Bakunin, and J. Persoz and N. Bloch, that **phosphoric oxide** yields phosphoryl chloride, but H. Schiff said that phosphorus pentoxide readily absorbs the vapours of the pentachloride, forming the complex $P_2O_5.2PCl_5$, or $P_4O_5Cl_{10}$, *phosphorus pentoxydecachloride.* This reaction was also examined by C. Gerhardt, and C. Gerhardt and L. Chiozza. A. Geuther found that the pentachloride reacts with **hypophosphorous acid:** $H_3PO_2+3PCl_5=2POCl_3+2PCl_3+3HCl$; and with **phosphorous acid:** $H_3PO_3+3PCl_5=PCl_3+3POCl_3+3HCl$. H. Schiff said that the pentachloride does not react with heated **metaphosphoric acid.** A. Geuther, however, represented the reaction: $HPO_3+2PCl_5=3POCl_3+HCl$; with pyrophosphoric acid, $H_4P_2O_7+5PCl_5=7POCl_3+4HCl$, or $H_4P_2O_7+PCl_5=2HPO_3+POCl_3+2HCl$; and with orthophosphoric acid, $H_3PO_4+3PCl_5=4POCl_3+3HCl$. H. Schiff said that the reaction **phosphoric acid** is very slow. R. Weber found that **sodium hydrophosphate** is decomposed by the vapour of phosphorus pentachloride. A. Geuther and A. Michaelis found a reaction with **pyrophosphoryl chloride:** $P_2O_3Cl_4+PCl_5=3POCl_3$. E. Baudrimont represented the reaction with **thiophosphoryl chloride:** $5PSCl_3+3PCl_5=3PBr_5+5PSCl_3$; and R. Weber, the reaction with **phosphorus pentasulphide,** $P_2S_5+3PCl_5=5PSCl_3$. E. Baudrimont, and H. Goldschmidt represented the reaction between powdered **arsenic** and the pentachloride by $4As+6PCl_5=4AsCl_3+6PCl_3$. M. Hurtzig and A. Geuther found that the reaction with **arsenic trioxide** results in the formation of arsenic trichloride, but no oxychloride, and with **arsenic pentoxide:** $As_2O_5+5PCl_5=2AsCl_3+2Cl_2+5POCl_3$—A. Michaelis said that arsenic pentoxide does not react with phosphorus pentachloride at 200°. T. E. Thorpe showed that with **arsenic trifluoride,** phosphorus pentafluoride is formed: $5AsF_3+3PCl_5=5AsCl_3+3PF_5$. A. W. Cronander said that **arsenic trichloride** reacts with the pentachloride, forming *arsenious phosphoctochloride,* $PCl_5.AsCl_3$, and *arsenic phosphodecachloride,* $AsCl_5.PCl_5$. E. Baudrimont found that the **arsenides** are decomposed when heated with phosphorus pentachloride; *realgar,* AsS, easily, but the following with difficulty: mispickel, FeAsS; *speiss cobalt,* $(Co,Ni,Fe)As_2$; *proustite,* Ag_3AsS_3; *pyrargyrite,* Ag_3SbS_3; *bournonite,* $CuPbSbS_3$; *fahlerz,* $(Cu_2,Ag_2,Fe,Zn)_3\{(As,Sb)S_3\}_2$; and *arsenical iron,* $FeAs_2$. E. Baudrimont said that powdered **antimony** reacts with the pentachloride more readily than does arsenic, forming antimony and phosphorus trichlorides. R. Mahn found that **stibine** produces phosphorus and antimony trichlorides, and hydrogen chloride. H. Schiff found that **antimony pentoxide** is not attacked when heated in contact with the pentachloride. E. Baudrimont observed that **antimony trichloride** forms a complex with phosphorus pentachloride, and R. Weber, and A. W. Cronander showed that both **antimony pentachloride** and trichloride form *antimony phosphodecachloride,* $SbCl_5.PCl_5$. T. Karantassis found that phosphorus pentachloride reacts with antimony triiodide liberating iodine and forming phosphorus trichloride, and the complex, $PCl_5.2SbCl_5$—*antimony phosphopentadecachloride*—$6PCl_5+2SbI_2=5PCl_3+2I_2+PCl_5.2SbCl_5$. E. Glatzel found **antimony trisulphide** is converted into this antimonyl sulphide.

H. Schiff observed that **potassium cyanide,** and **potassium ferrocyanide** are not decomposed by phosphorus pentachloride; but with **potassium thiocyanate,** a little sulphur monochloride, thiophosphoryl chloride, potassium chloride, sulphur, and phosphorus trichloride are formed. G. Gustavson found that some carbonyl chloride is produced when **sodium carbonate** is heated with the pentachloride. The use of phosphorus pentachloride for chlorinating **organic compounds** has been discussed by Lassar Cohn. It is in general use for replacing hydroxyl groups by chlorine, *e.g.* $(CH_2.COOH)_2+2PCl_5=(CH_2.CO.Cl)_2+2POCl_3+2HCl$; and with the acid anhydrides, $(CH_2CO)_2O+PCl_5=POCl_3+(CH_2.CO.Cl)_2$. The alcohols furnish the alkyl chlorides; and the amides their chlorine derivatives; the carbonyl oxygen of the aldehydes and ketones is replaced by Cl_2; chloral forms $CCl_3.CHCl_2$; etc. These reactions were investigated by G. F. Gerhardt, A. Cahours, A. Béchamp, M. Lies-Bodart, B. Rathke, E. Paterno, C. A. Wurtz, etc. C. T. Liebermann and L. Landshoff found that with ether the complex $(C_2H_5)_2O.3PCl_5$ is formed.

According to R. Mahn, **silane** slowly reduces phosphorus pentachloride to the trichloride. R. Weber said that **silica** is converted to silicon tetrachloride—the reaction with quartz is slow. R. Weber found that **titanium dioxide** yields a volatile chloride, and J. Tuttscheff showed that the complex *titanium phosphoenneachloride*, $TiCl_4.PCl_5$, is formed. S. R. Paijkul obtained *zirconium phosphotridecachloride*, $2ZrCl_4.PCl_5$, by the action of **zirconium tetrachloride** on phosphorus pentachloride in a sealed tube at 240°. According to G. Gustavson, when **boric oxide** is heated with the pentachloride for 3 or 4 days at 140°, boryl chloride is first formed, and later boron trichloride; J. Tarible found that with **boron tribromide,** a complex *boron phosphopentachlorohexabromide*, $2BBr_3.PCl_5$, is formed.

Phosphorus pentachloride transforms many **metals** into chlorides, and sometimes the excess unites with the metal chloride to form a complex—phosphorus trichloride is simultaneously formed. If the temp. is high enough, a metal phosphide may be formed. H. Davy found that if **potassium** is heated in the vapour of phosphorus pentachloride there is a lively combustion. A. C. Vournasos observed that the pentachloride reacts like the trichloride towards potassium. E. Baudrimont showed that cold **sodium** in contact with phosphorus pentachloride acquires a protective rind of sodium chloride. Molten sodium may inflame and detonate in contact with the pentachloride, forming phosphorus trichloride, but if the sodium is in excess, sodium phosphide is formed. According to H. Goldschmidt, **copper** reacts: $2Cu+PCl_5=2CuCl+PCl_3$, if an excess of the metal is present: $13Cu+2PCl_5=Cu_3P_2+10CuCl$; with **silver,** $2Ag+PCl_5=2AgCl+PCl_3$; and, according to E. Baudrimont, with **gold,** auric and phosphorous chlorides are formed. E. Baudrimont, W. T. Casselmann, and H. Goldschmidt found that with warm **zinc,** zinc and phosphorous chlorides are readily produced; but with the red-hot metal, zinc phosphide may be produced; E. Baudrimont found that **cadmium** behaves like zinc; and H. Goldschmidt represented the reaction with **mercury:** $Hg+PCl_5=HgCl_2+PCl_3$—*vide infra*, mercuric chloride. He also represented the reaction with **aluminium:** $2Al+3PCl_5=2AlCl_3+3PCl_3$. E. Baudrimont said that if the aluminium is red-hot, the phosphide may be produced as well; the aluminium chloride forms a complex with phosphorus pentachloride. The reaction was also studied by C. Matignon. E. Baudrimont found that **tin** forms stannous chloride which in turn forms a complex; with the pentachloride no phosphide was observed when the reaction occurs at a high temp. H. Goldschmidt symbolized the reaction: $Sn+2PCl_5=SnCl_4+2PCl_3$. E. Baudrimont said that with **iron** filings, ferrous, ferric, and phosphorous chlorides are formed, and the excess of the pentachloride forms a complex with ferric chloride. H. Goldschmidt represented the reaction: $Fe+PCl_5=FeCl_2+PCl_3$, and with the pentachloride in excess, ferric chloride is formed. M. M. Sobel said that phosphorus pentachloride fumes attacked every single metal tested up to 200°; but not so with **nickel,** and it has only a slight effect on **monel metal.** E. Fink found that with **palladium** and phosphorus pentachloride in a sealed tube, at 250°, a complex is formed. E. Baudrimont found that spongy **platinum** is easily converted into the tetrachloride which forms a complex with the excess of phosphorus pentachloride. P. Schützenberger thus obtained *platinous phosphoheptachloride*, $PtCl_2.PCl_5$. These reactions were studied by A. Rosenheim and co-workers. W. R. Hodgkinson and F. K. S. Lowndes showed that a platinum wire heated electrically in the vapour of phosphorus pentachloride forms a fusible platinum phosphide. G. Geisenheimer found that the pentachloride does not attack **iridium.** M. F. Schurigin, however, found both iridium and **ruthenium** are attacked at 300°, forming respectively *iridium triphosphododecachloride*, $IrCl_3.3PCl_3$, and *ruthenium pentaphosphoenneadecachloride*, $Ru_2(PCl_3)_5Cl_4$.

The **metal oxides** decompose at a red-heat in the vapour of phophorus pentachloride, forming the metal chloride and phosphoryl chloride. Thus, R. Weber observed that **magnesium oxide** so reacts with brilliant incandescence; **cadmium oxide** is likewise decomposed; and **aluminium oxide** produces a phosphochloride—

corundum and **spinel** are but slowly attacked. R. Weber found that **stannic oxide** forms stannic chloride. H. Schiff found that **chromic oxide** is converted into the violet chloride ; and **molybdenum trioxide** acts in the cold, forming white crystals of acid molybdenum chloride, and a sublimate of molybdenum trichloride, and, according to A. Piutti, the complex $MoCl_5.POCl_3$. E. F. Smith and G. W. Sargent heated molybdenum trioxide in the vapour of phosphorus pentachloride and chlorine, and obtained first phosphoryl chloride, and then the complex *molybdenum phosphodecachloride*, $MoCl_5.PCl_5$; no sign of molybdenum hexachloride was observed. A. W. Cronander found that **chromyl chloride** forms violet *chromic phosphooctochloride*, $CrCl_3.PCl_5$; and H. Schiff said violet chromic chloride and chlorine are the products of the reaction. J. Persoz and N. Bloch said that **tungsten trioxide** forms *tungsten trioxyphosphopentachloride*, $WO_3.PCl_5$; C. F. Gerhardt, C. H. Ehrenfeld, and H. Schiff and A. Piutti said that a sublimate of tungsten oxychloride is formed; and N. Teclu, that tungsten hexachloride and phosphoryl chloride are formed. A. W. Cronander found that **tungsten pentachloride** forms *tungsten phosphoenneachloride*, $WCl_4.PCl_5$; and with **uranium trioxide** in a sealed tube, yellow *uranium phosphodecachloride*, $UCl_5.PCl_5$, is formed. R. Weber found that **manganese oxide** is decomposed ; **ferric oxide** forms a complex ferric phosphochloride ; and that **titaniferous iron, chrome-ion,** and **franklinite** are decomposed.

H. Schiff said that **potassium chloride, bromide, or iodide** is not decomposed ; and A. W. Cronander added that the **alkali chlorides** do not form complex salts with phosphorus pentachloride. L. Pfaundler found that molten **silver fluoride** and the vapour of phosphorus pentachloride furnish phosphorus pentafluoride and silver chloride. L. Lindet found that with **auric chloride** the complex *auric phosphoenneachloride*, $AuCl_4.PCl_5$, is formed. E. Baudrimont prepared a complex with **mercuric chloride,** *mercuric phosphohexadecachloride*, $3HgCl_2.2PCl_5$, as a sublimate, by heating mercury or a chloride with phosphorus pentachloride. A. W. Cronander obtained the complex *molybdenum phosphodecachloride*, $MoCl_5.PCl_5$, when **molybdenyl chloride** is heated in the vapour of phosphorus pentachloride ; if the temp. is not so high, *molybdenum diphosphotetradecachloride*, $MoCl_4.2PCl_5$, is formed. He also obtained with **ferrous or ferric chloride** the complex *ferric diphosphoctochloride*, $FeCl_3.PCl_5$. According to R. Weber, and E. Baudrimont, the **metal sulphides** react with phosphorus pentachloride, forming thiophosphoryl chloride, the metal chloride, sulphur monochloride, and maybe a thiophosphate. E. Baudrimont found that **potassium sulphide** forms potassium chloride, thiophosphoryl chloride, and phosphorus pentasulphide ; analogous products are obtained with **calcium sulphide,** and **barium sulphide.** R. Weber found that **bismuth sulphide ; sphalerite,** ZnS ; **galena,** PbS ; and **marcasite,** FeS_2, are easily and completely decomposed. R. Weber found that **barytes** is decomposed when heated in the vapour of phosphorus pentachloride ; C. F. Gerhardt found that anhydrous **alum** furnishes a phosphate and hydrogen chloride, but no phosphoryl chloride. L. Carius observed that **lead sulphate** forms lead phosphate and sulphuryl chloride, while A. Michaelis obtained sulphur dioxide, chlorine, and phosphoryl chloride with a little thionyl and pyrosulphuryl chlorides, and a trace of sulphuryl chloride. J. Persoz and N. Bloch found that with **mercuric sulphate,** the complex *phosphorus sulphatodecachloride*, $SO_2.2PCl_5$, is formed. C. F. Gerhardt said that the products are phosphoryl, sulphuryl, and mercuric chlorides.

§ 33. The Oxychlorides of Phosphorus

In 1847, C. A. Wurtz [1] obtained *phosphoryl chloride*, $POCl_3$, in his study of the action on phosphorus pentachloride, and since then a number of other oxychlorides have been reported—*e.g.* G. Gustavson's *metaphosphoryl chloridc*, PO_2Cl; A. Geuther and A. Michaelis' pyrophosphoryl chloride, $P_2O_3Cl_4$; and A. Besson's *phosphoryl monochloride*, POCl. In addition, G. N. Huntly showed that the reaction between phosphorus trichloride and phosphorus pentoxide at 200° is more complex than that represented by the simple equation: $POCl_3+P_2O_5=3PO_2Cl$, because pyrophosphoryl chloride is formed as well as another substance "which cannot have a simpler formula than $P_7O_{15}Cl_5$," and which "may prove to be a mixture." It might be added that a mixture or solid soln. $P_2O_5+5PO_2Cl$ has the required composition $P_7O_{15}Cl_5$.

The so-called **phosphoryl chloride,** $POCl_3$, or *phosphoryl trichloride*—when it is desired to distinguish it from the monochloride, POCl—or *phosphorus oxychloridc*, or *phosphoric oxychloride*, or *orthophosphoric chloride*, is formed in a great many reactions. Thus, it is produced during (i) *the oxidation of phosphorus trichloride* when heated in air (W. Odling [2]); and by the action of oxygen on the boiling trichloride (A. Michaelis). Other oxidizing agents may be used—*e.g.* ozone (I. Remsen); potassium chlorate (E. Dervin); sulphur trioxide (H. E. Armstrong, and A. Michaelis); selenium dioxide, thionyl chloride, or selenyl chloride (A. Michaelis); and nitrogen trioxide (A. Geuther and A. Michaelis). A. A. Vanscheidt and V. M. Tolstopiatoff made it by the simultaneous action of water and chlorine on phosphorus trichloride. This is affected by passing a stream of chlorine through phosphorus trichloride and adding, drop by drop, an equivalent quantity of water; the end of the reaction is recognized by the formation of phosphorus pentachloride and the yellow coloration of the liquid. The heat of the reaction maintains the liquid at the boiling point until the end; the boiling is then continued artificially for about half an hour. Phosphoryl chloride is produced during (ii) *the oxidation or hydrolysis* *of phosphorus pentachloride* when the vapour mixed with oxygen is heated to redness (E. Baudrimont); by the action of moist air or water in quantity insufficient to form orthophosphoric acid (C. A. Wurtz, and G. Oddo); by the action of acid hydrates (C. F. Gerhardt, and H. Schiff); sulphur dioxide (H. E. Armstrong); sulphur trioxide or the various sulphur oxychlorides (A. Michaelis); by potassium perchlorate, and by nitric acid (H. Schiff); by phosphorous oxide (T. E. Thorpe and A. E. H. Tutton); by phosphorus pentoxide (C. F. Gerhardt, H. Schiff and A. Piutti. J. Persoz and N. Bloch, and T. E. Thorpe); metaphosphoric acid (A. Geuther); pyrophosphoryl chloride (A. Geuther and A. Michaelis); by various metal oxides or oxygenated salts (L. Carius, A. Michaelis, J. Y. Buchanan, H. Schiff and A. Piutti, and N. Teclu); and by the action of oxygenated organic compounds (A. Cahours, and C. F. Gerhardt). (iii) The action of a small proportion of water or acetic acid on phosphorus trichlorodibromide was found by A. Geuther and A. Michaelis to yield phosphoryl chloride. Phosphoryl chloride is also produced (iv) *by the chlorination of phosphorus or the phosphorus oxides or hydrides*—thus, the action of chlorosulphonic acid on red phosphorus (K. Heumann and P. Köchlin); chlorine on phosphorus tetritoxide (A. Michaelis and M. Pitsch), phosphorus oxide (T. E. Thorpe and A. E. H. Tutton), or phosphoryl monochloride (A. Besson); sodium chloride (H. Kolbe and E. Lautemann) or carbon tetrachloride (G. Gustavson) on phosphoric oxide; chlorine on ethyl phosphate (H. Wichelhaus); and sulphuryl or thionyl chloride on phosphine (A. Besson). (v) *By the thermal decomposition of the oxychlorides*—*e.g.* by heating phosphoryl dichlorobromide, or pyrophosphoryl chloride.

C. F. Gerhardt prepared phosphoryl chloride by distilling phosphorus pentachloride with half its weight of thoroughly dried oxalic acid, or over one-fifth of its weight of boric acid. E. Dervin recommended oxidizing phosphorus trichloride with potassium chlorate: $KClO_3+3PCl_3=3POCl_3+KCl$. The reaction is somewhat violent; 500 grms. of pure phosphorus trichloride free from uncombined phosphorus are placed in a retort of 750–1000 c.c. capacity, connected with a reflux condenser, and 160 grms. of finely powdered potassium chlorate are added through the tubulure in quantities of about 4 grms. at a time, care being taken to wait each time until ebullition ceases before adding more chlorate. When the whole of the chlorate has been added, the liquid is distilled. The yield is very satisfactory, and the phosphoryl chloride contains but traces of chlorine. If too much chlorate be used, chlorine is produced: $2POCl_3+KClO_3=KCl+P_2O_5+3Cl_2$, and G. Oddo said that this usually occurs towards the end of the operation. F. Ullmann and A. Fornaro said that to avoid the formation of chlorine oxides, the chlorate should be quite dry; and to avoid risk of explosions, the chlorate should be covered with a little previously obtained phosphoryl chloride, and the phosphorus trichloride added gradually. A 95·6 per cent. yield can be obtained by this process.

According to J. Riban, when chlorine is passed over a mixture of normal calcium phosphate and carbon, or when chlorine and carbon monoxide are passed over normal calcium phosphate alone heated to incipient redness, small quantities of calcium chloride and metaphosphate are formed, but no further change takes place. If, however, a mixture of chlorine and carbon monoxide is passed over an intimate mixture of calcium phosphate and carbon (*e.g.*, bone-black), heated in a glass tube to 330°–340° in an oil-bath, phosphoryl chloride, calcium chloride, and carbon dioxide are produced. After some time, the calcium chloride formed interferes with the reaction, but if it is removed by washing, the phosphate can be completely decomposed. The carbon plays no chemical part in the reaction, and is found practically unaltered at the end of the experiment. It is, however, essential to the production of the reaction, and probably acts by condensing the gases in its pores. The reaction occurs in two stages, thus: $Ca_3P_2O_8+2CO+2Cl_2=CaP_2O_6+2CO_2+2CaCl_2$, and $CaP_2O_6+4CO+4Cl_2=2POCl_3+4CO_2+CaCl_2$. The reaction takes place slowly at 180°, and proceeds rapidly between 330° and 340°. Analogous processes were used by G. Erdmann, and A. Ogliagoro. E. I. du Pont de Nemours ct Cie. made it by the action of carbonyl chloride on a phosphate at say 300°–500°—

e.g. $FePO_4+3COCl_2=POCl_3+3CO_2+FeCl_3$. According to P. P. Budnikoff and E. A. Schiloff, for the reaction $\frac{1}{2}Ca(PO_3)_2+2CO+Cl_2\rightleftharpoons\frac{1}{2}CaCl_2+POCl_3+2CO_2+73{\cdot}8$ Cals., the equilibrium constant $K=p^2{}_{CO}p^2{}_{Cl_2}/p_{POCl_3}p^2{}_{CO_2}$; and $\log K=3{\cdot}8+1{\cdot}75T-16200T^{-1}$; and for the reaction: $\frac{1}{2}Ca(PO_3)_2+2COCl_2=2CO_2+POCl_3+\frac{1}{2}CaCl_2$, $K=p^2{}_{COCl_2}/p^2{}_{CO_2}p_{POCl_3}$, and $\log K=3{\cdot}4-1{\cdot}75\log T-5690T^{-1}$.

The physical properties of phosphoryl chloride.—Phosphoryl chloride is a clear, colourless, fuming liquid with a smell like that of phosphorus trichloride. C. A. Wurtz [3] gave 1·7 for the **specific gravity** of the liquid at 12°; H. Wichelhaus, 1·66; A. Cahours, 1·673 at 14°; D. I. Mendeléeff gave 1·662 at 19·5°; H. L. Buff, 1·6937 at 10°, 1·6887 at 14°–15°, 1·64945 at 51°, and 1·5091 at 110°; T. E. Thorpe, 1·71165–1·71185 at 0°, and 1·50967 at 107·23°—the b.p.; and T. E. Thorpe and A. E. H. Tutton, 1·71185–1·71190 at 0°. C. A. Wurtz found the **vapour density** to be 5·334 at 151°, 5·298 at 215°, and 5·295 at 275°. T. E. Thorpe obtained 1·13378 for the vol. of the liquid at the b.p. when the vol. at 0° is unity. For the **molecular volume** at the b.p., T. E. Thorpe obtained data between 101·37 and 101·57; E. B. R. Prideaux, 101·3; H. L. Buff, between 101·44 and 102·24; and E. Rabinowitsch, 100. O. Masson, S. Sugden, and J. A. Groshans studied the mol. vols. of the family of halides. According to W. Ramsay and J. Shields, the **surface tension** at 18° is 31·91 dynes per cm., and at 46·1°, 28·37 dynes per cm.; while the **specific cohesion** at 18° is $a^2=3{\cdot}88$ per sq. mm., and at 46·1°, 3·55 per sq. mm. The **surface energy** $\sigma(Mv)^{\frac{2}{3}}=647{\cdot}7$ ergs at 18°, and 588·0 ergs at 46·1°. N. von Kolossowsky studied the relation between the capillary constants and the heat of vaporization.

The **thermal expansion**, represented by the vol., v, at $\theta°$, when the vol. at 0° is unity, was found by T. E. Thorpe to be:

	0°	20°	40°	60°	80°	100°	107·23°
v . .	1·00000	1·02178	1·04471	1·06906	1·09507	1·12300	1·133615

and he represented the results by $v=1+0{\cdot}001064309\theta+0{\cdot}0000011266\theta^2+0{\cdot}0_8 5299\theta^3$. A. Geuther and A. Michaelis said that when the liquid is cooled to −10°, it can be solidified so as to furnish colourless, long, tabular or columnar crystals. The liquid is very liable to undercooling, but A. Besson found crystallization occurs when the surfused liquid is seeded with a crystal of phosphoryl chloride or chlorobromide. A. Geuther and A. Michaelis gave −1·5° for the **melting point**; A. Besson, +2°; and G. Oddo, +1·782°. The **boiling point** found by C. A. Wurtz, A. Cahours, H. L. Buff, and H. Wichelhaus approximated 110°; E. Dervin, and G. Oddo gave 107°–108°; T. E. Thorpe, 107·22°–107·23° at 760 mm.; P. Walden, 105·8° at 753 mm.; and F. Ullmann and A. Fornaro, 104·5°–105·5° at 783 mm. W. Ramsay and J. Shields gave 329° for the **critical temperature**; and D. A. Goldhammer, 331·8°. The effect of phosphoryl chloride on the b.p. and f.p. of a number of solvents has just been indicated. G. Oddo gave 69 for the f.p. constant; and 21·3 cals. for the **heat of fusion**; and P. Walden, 52·7 cals. for the **heat of vaporization.** The **heat of formation** found for the liquid by J. Thomsen is (P,O,3Cl)=146·0 Cals.; M. Berthelot and W. Louguinine gave 143·9 Cals., and M. Berthelot, 145·9 Cals. J. Thomsen also found for $(PCl_3,O)=70{\cdot}66$ Cals., and for the **heat of solution,** or decomposition by water, 72·19 Cals., and M. Berthelot and W. Louguinine found that one eq. of phosphoryl chloride develops 74·7 Cals. when mixed with water, and with a (1 : 50) soln. of potassium hydroxide, 148·7 Cals. J. C. Thomlinson made some inferences about the constitution from the thermochemical data.

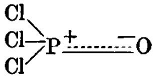
C. A. Wurtz found the liquid refracts light strongly. W. A. Miller examined the **absorption spectrum** of the liquid and showed that it completely absorbs the so-called chemical rays. H. L. Buff showed that the liquid is a non-conductor of electricity; while P. Walden found that at 105·0° and 753 mm. press. the sp. **electrical conductivity** is 0·0000022 mho, and is about equal to that of water of an average degree of purity. If the liquid has been in contact with moist air, the conductivity may rise 10 or 100 times this value. W. Finkelstein measured the **decomposition potential** of the oxychloride dissolved in bromine. H. Schlundt gave 13·9 for the **dielectric constant** at 22°.

Analyses of phosphoryl chloride by C. A. Wurtz,[4] J. H. Gladstone, A. Cahours, C. F. Gerhardt, T. E. Thorpe, G. Oddo, E. Dervin, and I. Remsen agree with the empirical formula $POCl_3$. The vapour density determinations of C. A. Wurtz, and A. Cahours are in agreement with the simple molecular formula $POCl_3$. W. Ramsay and J. Shields found no sign of the association of the molecules of the liquid when tested by the surface tension rule. The observations of G. Oddo and co-workers on the raising of the b.p. of soln. of phosphoryl chloride in carbon tetrachloride indicate that the molecule is more than doubled; while in benzene, and in carbon disulphide, there is a partial association of the simple molecules. The effect on the b.p. of chloroform, and ether agrees with the simple molecule. The mol. wt. for the doubled molecule is 307, and for the single molecule, 153·5. The means of the observed values are:

	CCl_4 (b.p.)	C_6H_6 (b.p.)	CS_2 (b.p.)	$CHCl_3$ (b.p.)	$(C_2H_5)_2O$ (b.p.)	C_6H_6 (f.p.)
Mol. wt.	332	298	232	161	152	151

E. Mameli found the effect of phosphoryl chloride on the f.p. of chloroacetic acid indicates a mol. wt. less than normal at low conc., and, increasing with conc., exceeds the normal value with a 1·3 per cent. conc.

There are two possible modifications of phosphoryl chloride, $Cl_2P.OCl$, and $Cl_3P : O$; in one, the phosphorus atom is tervalent, and in the other, quinquevalent —*vide supra*, the at. wt. of phosphorus. All attempts to isolate isomeric forms have failed. A. Michaelis and W. la Coste, however, did prepare derivatives of the two isomers, namely, phenoxydiphenylphosphine, $(C_6H_5)_2P.O.C_6H_5$, and phosphoryl triphenyl, $(C_6H_5)_3P : O$. The former is a thick, oily liquid which is readily acted upon by bromine, oxygen, sulphur, and selenium, and yields crystalline addition products with the alkyl halides; whereas the latter is a solid of m.p. 153·5°, and it resists the action of the agents just indicated. T. E. Thorpe and A. E. H. Tutton found that the phosphoryl chloride derived from phosphoric oxide is identical with that derived from phosphorous oxide. H. Wichelhaus thought that the constitution of phosphoryl chloride must be $Cl_2 : P.OCl$ because it is obtained by the action of chlorine on ethoxyphosphorus dichloride, $C_2H_5O.PCl_2$, in which it is highly probable that the oxygen is directly united with the phosphorus; the assumption is made that the reaction proceeds: $C_2H_5O.PCl_2+Cl_2 = C_2H_5Cl+ClO.PCl_2$, but A. Geuther and A. Michaelis have pointed out that it is possible the chlorine acts first by forming phosphorus trichloride: $C_2H_5O.PCl_2 + Cl_2 = C_2H_5OCl+PCl_3$; and the products of the reaction interact: $PCl_3+C_2H_5OCl = C_2H_5Cl+POCl_3$. T. E. Thorpe's conclusion that the sp. vol. of the contained phosphorus agrees with a tervalent phosphorus atom was shown by W. Ramsay and D. O. Masson to be ill-founded. The generally accepted formula $O : P : Cl_3$, based upon the quinquevalency of phosphorus, is not therefore inconsistent with H. Wichelhaus' reaction. It agrees with the formation of phosphoric acid when phosphoryl chloride is treated with water. It is also in agreement with B. Reinitzer and H. Goldschmidt's study of the action of phosphoryl chloride on the metals; no signs of any difference in the nature of the three chlorine atoms were observed; in all cases either none, or all three chlorine atoms were taken up by the metal. This agrees with the work of R. M. Caven, who progressively substituted the chlorine atoms in different ways with organic radicles and was not able to find any evidence justifying the assumption that the chlorine atoms are differently oriented within the molecule. He added: the centre of gravity of the three chlorine atoms lie at the angles of an equilateral triangle; and if an imaginary line is drawn through the centre of this triangle and at right angles to its plane, the centres of gravity both of the phosphorus atom and of the oxygen atom are situated in this line. E. B. R. Prideaux represents the electronic structure of phosphoryl chloride:



in which both electrons are contributed by the phosphorus atom, which has only half share in a pair originally belonging wholly to it, and is therefore positively charged—*vide supra*, phosphorus pentachloride—while the oxygen atom, having half a share in the same pair of electrons, to which it has not contributed, is negatively charged. A. E. Makovetzky made observations on the molecular structure; and H. Henstock, on the electronic structure.

The chemical properties of phosphoryl chloride.—H. P. Cady and R. Taft[5] studied a number of electrolytic reducing reactions with phosphorus oxychloride as a solvent, for soln. of potassium iodate, and ferric chloride are reduced although no hydrogen is present. C. A. Wurtz represented the action of **water** on phosphoryl chloride by the equation: $POCl_3+3H_2O=H_3PO_4+3HCl$. According to A. Besson, if a current of moist air is passed through phosphoryl chloride, a series of intermediate products of the oxidation to phosphoric acid are formed: (i) $2POCl_3+H_2O=2HCl+P_2O_3Cl_4$; (ii) $POCl_3+H_2O=2HCl+PO_2Cl$; and (iii) $POCl_3+3H_2O=3HCl+H_3PO_4$. G. Oddo also said that with one or two molecular parts of water, pyrophosphoryl chloride is formed along with some phosphoric acid, and that the proportion of the latter increases with that of the water. The speed of the reaction with water was measured by G. Carrara and I. Zoppellari as in the analogous case of phosphorus trichloride (*q.v.*); the velocity constant $k=0{\cdot}0000348$.

H. Schiff, and J. H. Gladstone observed no reaction between phosphoryl chloride and **chlorine, bromine,** or **iodine.** W. Biltz and E. Meinecke found that phosphoryl chloride is only slightly soluble in liquid chlorine. G. Oddo and M. Tealdi said that phosphoryl chloride dissolves **iodine monochloride.** A. Besson found that dry **hydrogen bromide** does not act at the b.p. of the chloride, and in a sealed tube, there is only a little action, but if the mixed vapours be passed through a tube at 400°–500°, the mixed and substitution products $POCl_2Br$, $POClBr_2$, $POBr_3$, and PBr_5 are said to be formed. He also found that **hydrogen iodide** dissolves in the liquid chloride and forms phosphorus triiodide and metaphosphoric acid—possibly also a little oxyiodide. H. Schiff found that phosphoryl chloride liberates iodine from **potassium iodide.** P. Walden also found that phosphoryl chloride dissolves the **alkali iodides,** forming yellow soln., also **manganese, cadmium, mercuric, and stannic iodides.** According to W. Spring, when the chloride is added to a cold soln. of **potassium chlorate,** a yellowish-green gas, possibly chlorine, is evolved; and G. Oddo represented the reaction: $KClO_3+2POCl_3=P_2O_5+3Cl_2+KCl$.

H. Prinz observed no reaction between phosphoryl chloride and **sulphur** when the mixture is heated in a sealed tube at 200° for a long time. C. A. Wurtz observed no reaction between **hydrogen sulphide** and the chloride when the mixture is exposed to sunlight; but A. Besson said that if a soln. of dry hydrogen sulphide in phosphoryl chloride be allowed to stand for some time, at 0°, there is a reaction: $2POCl_3+3H_2S=6HCl+P_2O_2S_3$; and at 100°, $2POCl_3+H_2S=2HCl+P_2O_2SCl_4$. G. Oddo and M. Tealdi found **sulphur monochloride and monobromide** dissolve in phosphoryl chloride. L. Carius represented the reaction with **calcium sulphite** at 150°, $2POCl_3+3CaSO_3=3SOCl_2+Ca_3(PO_4)_2$, but E. Divers said that no oxychloride of sulphur is formed when calcium, **sodium, or lead sulphite** reacts with phosphoryl chloride: $2POCl_3+6CaSO_3=3CaCl_2+Ca_3(PO_4)_2+6SO_2$. A. Michaelis represented the reaction at 160° with **sulphur trioxide:** $6SO_3+2POCl_3=P_2O_5+3S_2O_5Cl_2$; G. Oddo and A. Casalino studied the f.p. of the binary system: $POCl_3$–SO_3—*vide* sulphur trioxide; and S. Williams, and A. Michaelis, with **sulphuric acid:** $2H_2SO_4+POCl_3=2SO_2(OH)Cl+HPO_3+HCl$. L. Carius represented the reaction with **sulphates:** $3PbSO_4+2POCl_3=3SO_2Cl_2+Pb_3(PO_4)_2$, but A. Michaelis could not verify this. K. Kraut observed no reaction with **thiosulphates.** A. Besson observed no reaction in the cold with **hydrogen selenide,** but, at 110°, $4POCl_3+5H_2Se=10HCl+P_2Se_5+2PO_2Cl$. A. Michaelis observed that with **selenyl chloride,** phosphorus pentoxide and selenium tetrachloride are formed. V. Lenher found that when warmed with **tellurium dioxide,** tellurium tetrachloride is formed; and with an excess of phosphoryl chloride, the complex *tellurium phosphorylheptachloride,* $TeCl_4.POCl_3$.

C. A. Wurtz found that a white solid is produced when **ammonia** reacts with phosphoryl chloride; and H. Schiff represented the reaction: $POCl_3+6NH_3=PO(NH_2)_3+3NH_4Cl$. J. H. Gladstone found that at 0°, *phosphoryl dichloroamide,* $PO(NH_2)Cl_2$, is formed by a reaction which may be symbolized: $POCl_3+2NH_3=POCl_2(NH_2)+NH_4Cl$; and at ordinary temp. there is a slow formation of phosphoryl chlorodiamide, $PO(NH_2)_2Cl$, by the reaction: $POCl_3+4NH_3=POCl(NH_2)_2+2NH_4Cl$—this change is rapid at 100°. When these substitution products are heated, they decompose $POCl_2(NH_2)=2HCl+N\equiv PO$; and $POCl(NH_2)_2=NH_4Cl+N\equiv PO$. H. Perpérot mixed soln. of phosphoryl chloride and of ammonia in carbon tetrachloride, and obtained impure **phosphoryl hexamminotrichloride,** $POCl_3.6NH_3$—*vide supra,* phosphorus trichloride. If phosphoryl chloride be sat. with ammonia, or mixed with **ammonium chloride,** heated to 100°–220°, and the product treated with water, diamido- and triamido-pyrophosphoric acids are formed (*q.v.*). F. E. Brown and J. E. Snyder found that phosphoryl chloride and **vanadium oxytrichloride** are miscible in all proportions, but almost immediately a reaction sets in, and a brown precipitate forms. A. Mente also studied these reactions, and with **ammonium carbonate** he observed no formation of phosphoryl triamide. E. J. Mills found that phosphoryl chloride reacts with **nitrates,** forming the corresponding metal chloride, phosphorus pentoxide, etc. H. Schiff, and J. H. Gladstone observed no reaction with **phosphorus,** but at 200°–250° in a sealed tube, B. Reinitzer and H. Goldschmidt said that there is a vigorous reaction resulting in the formation of phosphorus tetritoxide (*q.v.*): $4P+POCl_3=P_4O+PCl_3$. H. Schiff, and J. H. Gladstone said that phosphoryl chloride does not react with **phosphine;** and A. Besson said that there is no reaction with cold **phosphonium bromide,** but in a sealed tube at 150°, phosphorus hemioxide is formed (*q.v.*); and with **phosphonium iodide,** phosphorus diiodide and metaphosphoryl chloride are formed. G. Oddo and M. Tealdi observed that **phosphorus trichloride and pentachloride** as well as **phosphorus tribromide and pentabromide** dissolve in this menstruum. G. Gustavson heated equimolar proportions of phosphoryl chloride and **phosphorus pentoxide** to 200° in a sealed tube for 36 hrs., and represented the resulting formation of metaphosphoryl chloride: $P_2O_5+POCl_3=3PO_2Cl$. A. Geuther said that phosphoryl chloride does not react with **phosphoric acid** in the cold, but when heated with a large proportion of the chloride metaphosphoric acid is formed: $2H_3PO_4+POCl_3=3HPO_3+3HCl$; and with a small proportion of the chloride, pyrophosphoric acid is produced: $5H_3PO_4+POCl_3=3H_4P_2O_7+3HCl$; the reaction with **pyrophosphoric acid** is very slow: $2H_4P_2O_7+POCl_3=5HPO_3+3HCl$; with **phosphorous acid:** $2H_3PO_3+3POCl_3=3HPO_3+2PCl_3+3HCl$; and with **hypophosphorous acid:** $6H_3PO_2+3POCl_3=3HPO_3+2H_3PO_3+4P+9HCl$. H. Schiff observed no reaction with **silver phosphate.** L. Carius obtained thiophosphoryl chloride and phosphorus pentoxide by heating to 150° a mixture of **phosphorus pentasulphide** and phosphoryl chloride. B. Reinitzer and H. Goldschmidt found that with **arsenic** at 250°, phosphorus and arsenic trichlorides, phosphorus pentoxide, and pyrophosphoryl chloride are formed. A. Michaelis observed no reaction with **arsenic trioxide** at 160°. G. Oddo and M. Tealdi observed that phosphoryl chloride dissolves **arsenic fluoride, chloride, and bromide;** and P. Walden, **arsenic triiodide,** and **antimony triiodide.** R. Weber obtained the complex *antimony phosphoryloctochloride,* $SbCl_5.POCl_3$, with **antimony pentachloride** and phosphoryl chloride; G. Oddo and M. Tealdi also obtained this compound;

and they found that **bismuth chloride and bromide** dissolve phosphoryl chloride.

J. Riban found that the vapour of phosphoryl chloride is decomposed by red-hot **carbon,** forming phosphorus trichloride. H. Schiff observed no reaction with **carbon dioxide ;** and H. Hübner and G. Wehrhane, none with **silver cyanide** at 180°. P. Walden found that numerous organic compounds dissolve in phosphoryl chloride ; and G. Oddo and M. Tealdi, that **carbon tetrachloride** dissolves in that menstruum. S. Cloez, and A. Geuther and F. Brockhoff found that the reaction between phosphoryl chloride and **sodium ethoxide** results in the formation of ethyl phosphate : $3C_2H_5ONa+POCl_3=3NaCl+PO(OC_2H_5)_3$. D. Balareff said that when the calculated quantity of **alcohol** is added drop by drop to phosphoryl chloride cooled in a freezing mixture, hydrogen chloride, and methyl or ethyl chloride are evolved when the mixture is warmed, and *alkyl metaphosphate* remains : $POCl_3+2C_2H_5OH =2HCl+POCl(OC_2H_5)_2$; and $POCl(OC_2H_5)_2=C_2H_5Cl+C_2H_5PO_3$. M. Riegel studied the action on **phenol.** As shown by A. Béchamp, H. Ritter, C. F. Gerhardt, H. Schiff, and I. I. Kanonnikoff, phosphoryl chloride is used for preparing chloro-derivatives of alcohol: $3C_2H_5OH+POCl_3=3C_2H_5Cl+H_3PO_4$; and with **sodium acetate :** $2CH_3COONa+POCl_3=NaCl+NaPO_3+2CH_3COCl$, but not from acetic acid alone. A. Béchamp and C. St. Pierre found that with silver acetate: $3CH_3COOAg+2POCl_3=3CH_3COCl+3AgCl+P_2O_5$. The use of phosphoryl chloride in organic chemistry was discussed by Lassar Cohn. G. Oddo and M. Tealdi found that phosphoryl chloride dissolves **silicon tetrachloride and tetrabromide.** A. Wehrlin and E. Giraud, and R. Weber prepared titanium phosphorylheptachloride, $TiCl_4.POCl_3$; and O. Ruff and R. Ipsen, *titanium diphosphoryldecachloride,* $TiCl_4.2POCl_3$, by the action of **titanium tetrachloride** on phosphoryl chloride. G. Gustavson found that with **boric oxide** and phosphoryl chloride in a sealed tube there is formed a complex *boron phosphorylhexachloride :* $B_2O_3+2POCl_3 =PBO_4+BCl_3.POCl_3$; and the same complex is formed by the action of **boron trichloride** on phosphoryl chloride. G. Oddo and M. Tealdi obtained *boron phosphoryl tribromotrichloride,* $BBr_3.POCl_3$, with **boron tribromide ;** and H. Moissan found that **boron triiodide** reacts vigorously with this chloride.

J. H. Gladstone observed no reaction between phosphoryl chloride and **potassium** at ordinary temp., and B. Reinitzer and H. Goldschmidt also observed no reaction with the alkali metals at 100°, but at 180°, in a sealed tube, the reaction is explosively violent. Finely divided **copper** reacts between 150° and 200°: $39Cu+10POCl_3=30CuCl+3Cu_3P_2+2P_2O_5$; and $P_2O_5+4POCl_3=3P_2O_3Cl_4$; with **silver** at 250°, $2Ag+POCl_3=Ag_2O+PCl_3$; $3Ag_2O+POCl_3=Ag_3PO_4+3AgCl$, or $5Ag_2O+2POCl_3=Ag_4P_2O_7+6AgCl$; $Ag_3PO_4+POCl_3=P_2O_5+3AgCl$; and $P_2O_5 +4POCl_3=3P_2O_3Cl_4$. At ordinary temp., **magnesium** reacts very slowly with phosphoryl chloride ; the reaction is energetic at 100°, and phosphorus trichloride, magnesium chloride and phosphide, and a red substance, possibly the suboxide, are formed ; **zinc** also reacts slowly at ordinary temp., and rapidly at 100°, $9Zn+4POCl_3=6ZnCl_2+3ZnO+P_4O$; and $4ZnO+2POCl_3=Zn(PO_3)_2+3ZnCl_2$; the reaction was also examined by W. T. Casselmann. G. Denigès said that if a good pinch of zinc powder is placed in a test-tube and one or two drops of phosphoryl chloride are added (the zinc must be in excess), there is frequently an instantaneous production of flame ; in all cases, on the addition of a little water, minute flames of hydrogen phosphide appear. With the trichloride, this reaction is not produced. According to B. Reinitzer and H. Goldschmidt, phosphoryl chloride and an excess of **mercury** at 290° react, forming mercuric chloride, a red phosphide, phosphorus trichloride, pyrophosphoryl chloride, and a trace of phosphorus pentoxide. At 100°, **aluminium** furnishes phosphorus trichloride, aluminium chloride and phosphate, and a red substance—possibly the suboxide. Only slight signs of a reaction were observed with **lead** at 250°, but **tin** reacts at 100°. At 100°–120°, **iron** filings react: $Fe+POCl_3=FeO+PCl_3$; $6FeO+2POCl_3 =3FeCl_2+Fe_3(PO_4)_2$; and $2POCl_3+Fe_3(PO_4)_2=3FeCl_2+2P_2O_5$.

According to H. Bassett and H. S. Taylor, **cuprous or cupric oxide** furnishes the chloride as the main product when in contact with phosphoryl chloride either at ordinary temp. or at 100°. On the other hand, when freshly ignited **calcium oxide** and phosphoryl chloride are mixed and allowed to stand at the ordinary temp., or gently boiled, a complex *calcium oxybisphosphoryltrichloride*, $CaO.2POCl_3$, is formed; while under different conditions *calcium oxytrisphosphoryltrichloride*, $CaO.3POCl_3$, may be produced; M. Garino and M. Raffaghello observed the formation of the complex *calcium dihydroxybisphosphoryltrichloride*, $Ca(OH)_2.2POCl_3$, with **calcium hydroxide.** There were also formed complexes $Ca(OH)_2.2POCl_2.2C_2H_5(NH_2)$, and $Ca(OH)_2.2POCl_2.2(C_2H_5)_2O$. Similarly, **magnesium hydroxide** forms *magnesium dihydroxybisphosphoryltrichloride*, $Mg(OH)_2.2POCl_3$. H. Bassett and H. S. Taylor found that **magnesium oxide** in a sealed tube at 110° forms either *magnesium oxybisphosphoryltrichloride*, $MgO.2POCl_3$, or *magnesium oxytrisphosphoryltrichloride*, $MgO.3POCl_3$; similarly, **zinc oxide** furnishes *zinc oxytrisphosphoryltrichloride*, $ZnO.3POCl_3$; **cadmium oxide** reacts at ordinary temp. or at 100°, forming cadmium chloride as the chief product; likewise also **mercuric oxide,** and alumina. On the other hand, **manganese oxide** furnishes *manganese oxytrisphosphoryltrichloride*, $MnO.3POCl_3$; while **ferric oxide,** and **cobaltous oxide** yield the metal chloride as in the case of copper, cadmium, mercury, and aluminium oxides. If the reactions occur in the presence of organic solvents—acetone, methyl benzoate, or ethyl acetate—complex pyrophosphoryl compounds are formed. M. Garino and M. Raffaghello obtained with **nickelous hydroxide** an impure complex, *nickelous dihydroxybisphosphoryltrichloride*, $Ni(OH)_2.2POCl_3$.

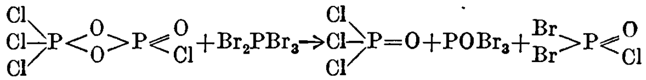
P. Walden found that phosphoryl chloride dissolves **auric chloride** in the cold. W. T. Casselmann found that phosphoryl chloride unites readily with many **metal chlorides,** thus, with **magnesium chloride** it forms magnesium phosphorylheptachloride, $2MgCl_2.POCl_3$; with **aluminium chloride** it forms *aluminium phosphorylhexachloride*, $AlCl_3.POCl_3$. G. Oddo and M. Tealdi obtained both these compounds. E. P. Köhler obtained with **aluminium bromide,** *aluminium phosphoryltribromotrichloride*, $AlBr_3.POCl_3$; H. Moissan obtained with **zinc fluoride,** zinc chloride and phosphoryl fluoride; and analogous products were obtained by A. Guntz with **lead fluoride**; while W. T. Casselmann obtained with **stannous chloride** the complex *stannous phosphorylheptachloride*, $2SnCl_2.POCl_3$; and also a complex with **stannic chloride,** $SnCl_4.POCl_3$, *stannic phosphorylheptachloride*, while G. Oddo and M. Tealdi represent as *stannic phosphorylhenachloride*, $2SnCl_4.POCl_3$. W. T. Casselmann obtained with **chromyl chloride** the products chromic oxide and chloride, and phosphoric acid. A. Piutti reported *molybdenum phosphorylhexachloride*, $MoCl_3.POCl_3$, to be formed by the action of **molybdenum trichloride** and phosphoryl chloride in a sealed tube at 170°. P. Walden, and G. Oddo found that sublimed **ferric chloride** forms a yellowish-brown soln. with phosphoryl chloride; and G. Oddo, that **platinic chloride** is dissolved by the menstruum.

A. Besson[6] prepared **phosphoryl monochloride,** POCl, by the action of a small quantity of water—whether liquid, or as atm. moisture—on phosphorus trichloride. The compound is isolated by distilling off the trichloride, at first on a water-bath and finally under low press. This oxychloride is a yellowish, hyaline solid of the consistency of paraffin, with an odour recalling that of the ordinary phosphoryl chloride. It is very hygroscopic, and dissolves in water with a strident noise, the products being hydrochloric acid, phosphorous acid, and a small quantity of an amorphous yellow solid. It is rapidly decomposed by light with formation of a pale yellow precipitate which changes to reddish-yellow if the action of light is prolonged. The oxychloride is insoluble in most solvents, but dissolves in phosphorous trichloride. It combines slowly with chlorine, and yields phosphoryl chloride, $POCl_3$. The yield of phosphorous oxychloride is always very small, probably because its formation is limited by its extremely hygroscopic nature.

A. Geuther and A. Michaelis[7] prepared **pyrophosphoryl chloride,** $P_2O_3Cl_4$, by the action of nitrogen trioxide or peroxide on well-cooled phosphorus trichloride—

the trichloride yields about one-tenth its weight of the pyrophosphoryl chloride. B. Reinitzer and H. Goldschmidt obtained it as a by-product of the action of copper, silver, mercury, phosphorus or arsenic on phosphoryl chloride; and G. N. Huntly, by the action of phosphorus pentoxide on phosphoryl chloride—the product $P_7O_{15}Cl_5$ was obtained at the same time, *vide supra*. A. Besson said that in the preparation of phosphorus hemioxide (*q.v.*) by the action of phosphonium bromide on phosphoryl chloride, when the filtrate is heated in vacuo, pyrophosphoryl chloride distilled off after the phosphoryl chloride—metaphosphoryl chloride remains as a residue. A. Besson also found that pyrophosphoryl chloride is formed by the action of a current of moist air on phosphoryl chloride, $2POCl_3+H_2O=2HCl+P_2O_3Cl_4$—some phosphoric acid and metaphosphoryl chloride are formed at the same time. He also heated 300 grms. of phosphoryl chloride and 30 grms. of water first on a water-bath, and then in a sealed tube at 100°. When the product is heated in vacuo, pyrophosphoryl and phosphoryl chlorides distil over, and metaphosphoryl chloride and phosphoric acid remain behind. When the distillate is heated in vacuo at 25°–30°, the phosphoryl chloride distils off, and about 5 grms. of pyrophosphoryl chloride remain. G. Oddo also prepared this chloride by heating a mixture of 2 mols of phosphorus pentachloride and 3 mols of water under 3 cms. press. between 125° and 127°.

Pyrophosphoryl chloride was analyzed by A. Geuther and A. Michaelis, G. Oddo, and G. N. Huntly, and the results are in accord with the empirical formula $P_2O_3Cl_4$. If pyrophosphoryl chloride has the symmetrical formula $Cl_2 : PO.O.PO : Cl_2$, the rupture of the molecule in the reaction $P_2O_3Cl_4=POCl_3+PO_2Cl$ must be attended by the transfer of a chlorine atom from one part to the other, and D. Balareff supposes that the unsymmetrical formula for the pyrophosphoryl chloride, $Cl_3 : P<O_2>PO.Cl$, best explains this reaction. The symmetrical and the unsymmetrical formulæ explain equally well the reaction with phosphorus pentachloride: $P_2O_3Cl_4+PCl_5=3POCl_3$, but with phosphorus pentabromide, the reaction is somewhat curious; with the unsymmetrical formula it is represented:



and with the symmetrical formula:

$$\begin{matrix}PO(Cl_2)\\PO(Cl_2)\end{matrix}>\boxed{O\ +\ Br_3P}Br_2\rightarrow POBr_3+\begin{matrix}POCl_2Br\\POCl_2Br\end{matrix}$$

A. Geuther and A. Michaelis consider this to be the strongest argument in favour of the symmetrical formula, but D. Balareff argues that the reaction is here so complex that it has not yet been made out whether $POCl_2Br$ alone is formed or whether phosphoryl chloride, $POCl_3$, is produced along with phosphoryl bromide, $POBr_3$. D. Balareff also considers that the chemical properties of pyrophosphoryl chloride agree very well with the unsymmetrical formula for the chloride, and the chemical properties of pyrophosphoric acid with the unsymmetrical formula $(HO)PO<O_2>P(OH)_3$.

Pyrophosphoryl chloride is a colourless, fuming liquid which remains liquid at temp. where phosphoryl chloride is solid. A. Besson did not solidify the liquid at —50°. A. Geuther and A. Michaelis gave 1·58 for the sp. gr. at 7°, and 210°–215° for the b.p. It cannot be distilled without some decomposition: $3P_2O_3Cl_4=4POCl_3+P_2O_5$; and A. Besson said that at 110° and 10 mm. press., the compound decomposes: $P_2O_3Cl_4=POCl_3+PO_2Cl$. A. Geuther and A. Michaelis said that water decomposes it faster than it does phosphoryl chloride, forming hydrochloric and phosphoric acids; alcohol reacts: $2P_2O_3Cl_4+4C_2H_5OH=4PO(OC_2H_5)Cl_2+2H_2O$, followed by $PO(OC_2H_5)Cl_2+2H_2O=PO(OC_2H_5)(OH)_2+2HCl$; phosphorus pentachloride reacts: $P_2O_3Cl_4+PCl_5=3POCl_3$; and phosphorus pentabromide: $P_2O_3Cl_4+PBr_5=2POBrCl_2+POBr_3$. M. Riegel studied its action on phenol.

H. Bassett and H. S. Taylor found that when lime is added to a soln. of phosphoryl chloride in acetone, ethyl acetate, methyl benzoate, or ethyl benzoate, which had been dried over calcium chloride and redistilled, a vigorous reaction occurred which in the first two cases was sufficient to cause the solvent to boil. Some hydrogen chloride is evolved during this process, and the lime passes into soln. The soln. on cooling deposits prismatic crystals of **calcium oxypyrophosphoryl chloride,** $CaO.P_2O_3Cl_4$, associated with two mols of the solvent ketone or ester: $CaO,P_2O_3Cl_4,2C_3H_6O$; $CaO,P_2O_3Cl_4,2C_4H_8O_2$; $CaOP_2O_3Cl_4,2C_8H_8O_2$; and $CaO,P_2O_3Cl_4,2C_9H_{10}O_2$. In agreement with this view is the fact that the organic part of the molecule can be changed by simple recrystallization from another solvent. Thus, by recrystallizing the ethyl acetate compound from acetone, the acetone compound is obtained, and *vice versa.* Similar compounds of the organic ester or ketone associated with **copper oxypyrophosphorylchloride,** $CuO.P_2O_3Cl_4$; **magnesium oxypyrophosphorylchloride,** $MgO.P_2O_3Cl_4$; **cadmium oxypyrophosphorylchloride,** $CdO.P_2O_3Cl_4$; and **manganese oxypyrophosphorylchloride,** $MnOP_2O_3Cl_4$, can be prepared. The formation of these organic compounds is brought about by traces of moisture present in the organic solvents, or which are absorbed during the course of the experiment, and there is some reason for thinking that the moisture acts preferably on the previously formed compound $CaO,2POCl_3$, rather than on the phosphoryl chloride. In any case, the organic compounds can be obtained equally well by treating the previously prepared compound, $CaO,2POCl_3$, with the organic solvent in which it dissolves, yielding a soln. from which the organic derivative of the compound $CaO,P_2O_3Cl_4$ crystallizes. The zinc and cobaltous compounds could not be obtained in a crystalline form.

G. Gustavson[8] prepared **metaphosphoryl chloride,** PO_2Cl, by heating eq. quantities of phosphorus pentoxide, and phosphoryl chloride in a sealed tube at 200° for 36 hrs.: $P_2O_5+POCl_3=3PO_2Cl$. G. N. Huntly could not obtain this substance in this way—he always obtained a mixture of pyrophosphoryl chloride and $P_7O_{15}O_5$, indicated above. T. E. Thorpe and A. E. H. Tutton obtained it by passing a current of chlorine not too quickly over phosphorous oxide: $P_4O_6+4Cl_2=2POCl_3+2PO_2Cl$. The phosphoryl chloride can be distilled from the metaphosphoryl chloride—10 grms. of phosphorous oxide yield about 14 grms. of phosphoryl chloride and 9 grms. of metaphosphoryl chloride. A. Besson observed that metaphosphoryl chloride is formed during the action of hydrogen selenide on phosphoryl chloride: $4POCl_3+5H_2Se=10HCl+P_2Se_5+2PO_2Cl$; as a by-product in the action of phosphonium bromide on phosphoryl chloride in the preparation of phosphorus hemioxide—*vide supra,* pyrophosphoryl chloride; by the action of moist air on phosphoryl chloride—*vide supra,* pyrophosphoryl chloride; and by heating pyrophosphoryl chloride at 110° and 10 mm. press.—*vide supra.* The syrupy mass was found by A. Besson to decompose when heated: $3PO_2Cl=POCl_3+P_2O_5$.

§ 34. The Phosphorus Bromides and Oxybromides

The observations of A. J. Balard,[1] H. Rose, A. Schrötter, and V. Merz and W. Weith on the union of bromine and phosphorus have been indicated in connection with phosphorus itself. W. Müller-Erzbach said that phosphorus has a smaller affinity for bromine than it has for chlorine. There are two well-defined bromides, analogous to the tri- and penta-chlorides; a heptabromide has been reported. A. Besson and L. Fournier attempted to prepare *phosphorus dibromide*, PBr_2, or P_2Br_4, analogous to the corresponding chloride and iodide, by the action of the silent discharge on a mixture of phosphorus tribromide and hydrogen, and by the action of hydrobromic acid on phosphorus dichloride, but without success. A reddish-yellow solid of indefinite composition was obtained, and this is supposed to be a decomposition product of the dibromide.

The formation and preparation of phosphorus tribromide.—A. J. Balard first prepared **phosphorus tribomide**, PBr_3, by very slowly adding bromine, drop by drop, to dry phosphorus. C. Löwig added small pieces of phosphorus to anhydrous bromine until the liquid is colourless, and the tribromide was distilled from the excess of phosphorus. A. Lieben said that if the phosphorus, etc., is well-cooled by a freezing mixture there is no risk of explosion. In order to avoid the risk of an explosion, H. Rose recommended introducing dry phosphorus into a glass tube sealed at the bottom and placed upright in liquid bromine contained in a wide-mouthed bottle, so that the bromine vapour may slowly come in contact with the phosphorus. The tribromide is also produced by slowly adding bromine to red phosphorus, and distilling the product; J. Volhard moderated the reaction by first moistening the phosphorus with phosphorus tribromide. R. Schenck, and A. C. Christomanos said that when an excess of phosphorus is employed the product is always contaminated with phosphatic products which cannot be removed by many rectifications; and R. Schenck preferred to use an excess of bromine which is more easily removed by fractional distillation. F. A. Kekulé dissolved 239·88 parts of bromine, and 31 parts of phosphorus separately in carbon disulphide; slowly mixed the products; and separated the solvent from the tribromide by distillation. This method was employed by J. Volhard, V. Rekschinsky, and G. Oddo and M. Tealdi, while A. C. Christomanos added that the solvent is not a suitable one since it is difficult to obtain pure, and it is liable to yield a product contaminated with sulphur compounds. A. C. Christomanos said that an 88 per cent. yield of tribromide of a high degree of purity can be obtained if bromine be allowed to act on yellow phosphorus, free from arsenic, under a layer of benzene free from thiophene. A. Lieben prepared the tribromide by passing the vapour of bromine in a current of carbon dioxide over dry phosphorus; allowing the product to stand for a day in contact with phosphorus; and distilling the decanted liquid. No considerable rise of temp. occurs so long as the bromine vapour is in contact with phosphorus. J. I. Pierre employed this process, but A. C. Christomanos added that the operation consumes a lot of time, the yield is poor, there is a loss of bromine, and the product is contaminated with other phosphatic products. C. Löwig passed the vapour of phosphorus over mercurous or mercuric bromide heated in a glass tube, and collected the product in a cooled receiver. The liquid was rectified by fractional distillation. He also observed the formation of a little tribromide by the action of phosphorus on warmed cyanogen bromide; A. Besson, by the action of hydrogen bromide on phosphorus trichloride; and E. Baudrimont, by passing carbon dioxide over phosphorus pentabromide heated in a flask on a water-bath.

The physical properties of phosphorus tribromide.—Phosphorus tribromide is a clear, mobile, fuming liquid with a smell recalling that of hydrogen bromide. A. C. Christomanos said that usually the liquid becomes faintly turbid on standing for some time on account of the separation of phosphorus held in soln. The soln. clears again if warmed up to near the b.p. The liquid colours the skin orange-yellow, and paper dark yellow or black, especially if warmed. J. I. Pierre gave 2·9249 for the sp. gr. of the liquid at 0°; T. E. Thorpe, 2·92311 at 0°, and 2·49541 at 172·9°, the b.p.; G. Carrara and I. Zoppelari, 2·9132 at 11°/4°; and A. C. Christomanos, 2·88467 at 0°, 2·85234 at 15°, and 2·82053 at 27°. O. Masson, S. Sugden, and J. A. Groshans studied the mol. vols. of the family of halides; and F. Ephraim calculated that a 10·8 per cent. expansion occurs during the formation of the tribromide. F. M. Jäger found for the sp. gr. referred to water at 4°, the surface tension, σ, in dynes per cm., the specific cohesion, a^2, per sq. mm., and the mol. surface energy, μ, in ergs per cm. in nitrogen gas:

	−20°	0°	20·8°	50·3°	75·7°	99·8°	154°	170°
Sp. gr. .	2·972	2·923	2·871	2·799	2·735	2·676	2·542	2·502
a^2 . .	3·14	3·12	3·05	3·01	2·90	2·74	2·28	2·14
σ . .	45·8	44·7	43·2	41·3	38·9	36·0	28·4	26·3
μ . .	927·0	916·8	894·7	870·0	832·1	781·4	637·9	597·0

R. Lorenz and W. Herz studied the relations between the surface tensions of the family of halides. H. Kopp gave for the mol. vol. at the b.p., 108·6; E. B. R. Prideaux, 108·8; T. E. Thorpe, 108·28; and E. Rabinowitsch, 111. The vap. density found by A. C. Christomanos was 135·44 for hydrogen unity, at 182°; and for air unity, 9·3589. This in conjunction with C. Löwig's analysis is in agreement with the formula PBr_3. G. Oddo and M. Tealdi found that the mol. wt. obtained from the effect on the f.p. of phosphoryl chloride is 271; and benzene, 261·8—the theoretical value for PBr_3 is 271. T. E. Thorpe, and J. I. Pierre observed that the thermal expansion is "extremely regular"; T. E. Thorpe gave for the vol. at different temp. when the vol. at 0° is unity:

	0°	40°	60°	80°	100°	120°	140°	172·9° (b.p.)
Vol. .	1·0000	1·0348	1·0530	1·0720	1·0961	1·1123	1·1340	1·17140

and he represented his results for the vol., v, at $\theta°$ by $v=1+0{\cdot}0_3841170\theta+0{\cdot}0_6542892\theta^2+0{\cdot}0_818893\theta^3$; and J. I. Pierre found for temp. between 0° and 100°, $v=1+0{\cdot}0_3847200\theta+0{\cdot}0_643672\theta^2+0{\cdot}0_82528\theta^3$; and between 100° and 175°, $v=1+0{\cdot}0_3824270\theta+0{\cdot}0_6914210\theta^2+0{\cdot}0_{10}55\theta^3$. D. I. Mendeléeff, and P. de Heen made observations on this subject. A. C. Christomanos found the coeff. of cubical expansion to be 0·0007554 at 15°, and 0·0007876 at 27°, so that the effect is greater than is the case with mercury. 1. I. Saslowsky studied the relation between the coeff. of expansion and the mol. structure; and N. de Kolossowsky, the relation between the coeff. of expansion and the latent heat of vaporization. A. J. Balard did not freeze the liquid at —12°, nor did J. I. Pierre at —13·6°; but A. C. Christomanos gave —41·5° for the f.p. at 761 mm. press. F. M. Jäger gave —50° for the f.p., and —40° for the m.p. J. I. Pierre gave 175·3° for the b.p. at 760·2 mm.; F. A. Kekulé, and H. Kopp, 175°; T. E. Thorpe, 172·9°; F. M. Jäger, 170·2° at 750 mm.; P. Walden, 172° and 757 mm.; G. Oddo and M. Tealdi, 170°; and A. C. Christomanos, 170·8° at 760 mm. and 171° at 761 mm. C. M. Guldberg calculated the critical temp. to be 441°. M. Berthelot gave for the heat of formation, $(P,3Br_{liq.})=PBr_{3liq.}+42·6$ Cals.; and M. Berthelot and W. Longuinine, $(P,3Br_{gas})=PBr_{3liq.}+54·6$ Cals., while one eq. of the tribromide in reacting with water yields 64·1 Cals., and with a (1 : 50) soln. of potassium hydroxide, 130·5 Cals. A. C. Christomanos found the index of refraction to be 1·6945 at 19·5° with Na-light. P. Walden said that phosphorus tribromide is a non-conductor of electricity, and does not ionize dissolved salts and acids; he also measured its conductivity in liquid sulphur dioxide and arsenic trichloride. H. Schlundt obtained 3·88 for the dielectric constant at 20°.

The chemical properties of phosphorus tribromide.—A. Besson and L. Fournier said that when a mixture of **hydrogen** and the vapour of phosphorus tribromide is exposed to the silent discharge, there is formed an unstable dibromide —*vide supra.* According to J. H. Gladstone, phosphorus tribromide is not attacked by **oxygen**; and A. C. Christomanos also found that oxygen has no appreciable action on the cold liquid, but E. Demole showed that if oxygen be passed through the boiling liquid, an explosion occurs after a certain time with the liberation of bromine, etc. He represented the reaction: $2PBr_3+O_2=2POBr+2Br_2$; $POBr+Br_2=POBr_3$; and $PBr_3+Br_2=PBr_5$; while A. C. Christomanos attributed the reaction to the liberation of bromine, and the combustion of the phosphorus with a yellowish flame of "blinding brilliance": $2PBr_3+5O=P_2O_5+3Br_2$. He also said that the tribromide is non-combustible, and does not ignite at ordinary temp., nor does the vapour from the boiling liquid inflame, though it does burn with a yellowish flame when in the vicinity of another flame—phosphorus pentoxide and bromine are formed. A. J. Balard, and C. Löwig said that in the presence of moisture, phosphorus tribromide reddens blue litmus; and A. J. Balard, and A. C. Christomanos found that the tribromide reacts with **water,** forming phosphorous and hydrobromic acids, and, if only a little water is employed, hydrogen bromide is evolved as a gas. The reaction, added C. Löwig, is slow at 8°, but very rapid at 35°. G. Carrara and I. Zoppelari found the velocity constant of the heterogeneous reaction to be 0·0111 at 5°, and 0·0212 at 10°.

A. J. Balard, and J. H. Gladstone found that the tribromide reacts with **chlorine**: $2PBr_3+3Cl_2=2PCl_3+3Br_2$; and, according to C. Löwig, it reacts with **bromine,** forming the pentabromide (*q.v.*). J. H. Gladstone, and A. C. Christomanos found that **iodine** dissolves in the liquid tribromide without reacting chemically. The liquid is cherry-red. A. Damoiseau observed that the tribromide is decomposed by conc. aq. soln. of **hydrobromic acid.** E. Baudrimont showed that thiophosphoryl bromide is formed when phosphorus tribromide is heated in contact with sulphur. U. Antony and G. Magri found that the tribromide dissolves in liquid **hydrogen sulphide,** forming a yellow, conducting soln. J. H. Gladstone represented the reaction with hydrogen sulphide: $2PBr_3+3H_2S=P_2S_3+6HBr$. G. N. Guam and J. A. Wilkinson observed that the soln. in liquid hydrogen sulphide is an electrical conductor.

H. Rose said that the tribromide behaves like the trichloride when treated with **ammonia**; and liquid ammonia, according to C. Hugot, reacts with the tribromide, forming phosphorus triamide (*q.v.*). A. Besson found that dry ammonia acts on a soln. of phosphorus tribromide in carbon tetrachloride, forming *phosphorus enneaamminotribromide,* $PBr_3.9NH_3$. A. Geuther and A. Michaelis observed that **nitrogen peroxide, and trioxide** react with the tribromide, forming phosphorus pentoxide and phosphoryl bromide. C. Löwig, R. Schenck, and A. C. Christomanos observed that the tribromide dissolves **phosphorus** which separates out when the soln. is decomposed by water—*vide supra,* red phosphorus. K. Kraut said that the tribromide reacts with **phosphorous acid** like the trichloride, but at a somewhat higher temp. P. de Wilde said that **phosphine** reacts quickly with the tribromide, forming hydrogen diphosphide (*q.v.*), and, added A. Besson, the reaction occurs even at —20°. A. Michaelis found that **thiophosphoryl bromide** dissolves in the liquid; and P. Walden, that the **trihalides of arsenic and antimony** are readily soluble in the cold liquid tribromide.

J. Tarible found that with **boron tribromide** much heat is developed and *boron phosphohexabromide*, $PBr_3.BBr_3$, is formed. A. C. Christomanos said that the liquid is very corrosive towards organic matter—leather, wood, paper, cork, rubber, etc.; he also found that phosphorus tribromide dissolves in **carbon disulphide, ether, acetone, chloroform,** and **benzene,** forming clear soln. without developing heat. When the ethereal soln. is evaporated, much hydrobromic acid is formed. P. Walden also showed that many **organic compounds** are soluble in the liquid bromide—*e.g.* hydrocarbons, acids, ketones, esters, tertiary amines, etc. A. C. Christomanos found that absolute **alcohol** reacts turbulently with the tribromide, without inflammation, forming traces of esters or phosphines. J. W. Walker and F. M. G. Johnson studied the action of methyl, ethyl, and *n*-propyl alcohols on phosphorus tribromide. The reactions are typified by $PBr_3+3CH_3OH=2CH_3Br+HBr+P(OH)_2(OCH_3)$. V. Auger found that phosphorus tribromide reacts with **methyl, ethyl, or propyl iodide** to form alkyl phosphines. A. C. Christomanos studied the action of the tribromide on **glycerol,** and **phenol.** R. Schenck found that **glass** is strongly attacked by the tribromide at an elevated temp.

A. C. Christomanos found that a small piece of **sodium** floats on the cold or warm liquid losing its metallic lustre; but if a little hot or cold water be sprinkled on the surface, there is a violent explosion; **sodium-amalgam** under similar conditions gives burning hydrogen; and **magnesium** acts like sodium, but the reaction is less violent and there is no explosion. A. Granger obtained copper phosphide by heating the tribromide with **copper** in a sealed tube; and when **iron, nickel, or cobalt** is heated in the vapour of the tribromide, the metal phosphide is formed. A. C. Christomanos found that **copper nitrate,** solid or in soln., reacts vigorously with the tribromide, and cuprous bromide, bromine, and nitrogen peroxide are formed; L. Lindet observed that when heated with **aurous bromide,** *aurous phosphotetrabromide*, $AuBr.PBr_3$, is formed. J. H. Gladstone observed an interchange of the halogens when phosphorus tribromide reacts with **mercuric chloride**; and H. Moissan represented the reaction with **zinc fluoride**: $3ZnF_2+2PBr_3=2PF_3+3ZnBr_2$; a similar reaction occurs with lead fluoride, but it proceeds more slowly. P. Walden found that the **stannic halides** dissolve in the cold liquid tribromide, and that with the iodide, the soln. is yellow. H. S. Fry and J. L. Donnelly found that phosphorus tribromide reacts like the trichloride towards **chromyl chloride.** G. Geisenheimer observed the complex *iridium triphosphododecabromide*, $IrBr_3.3PBr_3$; and M. F. Schurigen, *iridium phosphohexabromide*, $IrBr_3.PBr_3$, when the tribromide is heated with **iridium** in a sealed tube at 300°; and **ruthenium** under similar conditions yields *ruthenium pentaphosphoenneadecabromide*, $Ru_2(PBr_3)_5Br_4$.

H. Rose observed that phosphine forms a brownish-yellow precipitate with a soln. of mercuric bromide; and P. Lemoult observed that by the action of phosphine on a soln. of mercuric bromide in one of potassium bromide, a brown compound is formed, **phosphorus bromomercuriate,** $P(HgBr)_3.PHg_2Br$.

The formation and preparation of phosphorus pentabromide.—A. J. Balard first obtained **phosphorus pentabromide,** PBr_5, as a sublimate when an excess of bromine acts on phosphorus; and A. J. Balard, and C. Löwig obtained it by mixing theoretical proportions of phosphorus tribromide and bromine. W. Biltz and K. Jeep studied the thermal diagram of mixtures of phosphorus tribromide and bromine, Fig. 50, and obtained evidence of the existence of three polybromides, **phosphorus heptabromide,** $PBr_5.Br_2$; **phosphorus enneabromide,** $PBr_5.2Br_2$; and **phosphorus heptadecabromide,** $PBr_5.6Br_2$. The pentabromide can be obtained by metathetical reactions; thus, J. H. Gladstone found that liquid bromine sinks in liquid phosphorus trichloride without reacting, but if a little iodine is added, much heat is developed by the reaction: $2PCl_3+I_2+5Br_2=2PBr_5+2ICl_3$; H. Moissan showed that when phosphorus trifluoride is passed into bromine cooled to −15°, brown liquid phosphorus dibromotrifluoride is formed; this gradually decomposes: $5PF_3Br_2=3PF_5+2PBr_5$, the pentabromide remains in the tube, the pentafluoride escapes as a gas. A. Michaelis obtained it by the action of phosphorus pentachloride on thiophosphoryl bromide: $5PSBr_3+3PCl_5=5PSCl_3+3PBr_5$; A. Besson, by passing a mixture of the vapours of phosphoryl chloride and hydrogen bromide through a glass tube at 400°–500°; E. Demole. by the action of oxygen on boiling phosphorus tribromide—*vide supra;* and T. E. Thorpe and A. E. H. Tutton, by the action of bromine on phosphorous oxide in a sealed tube at ordinary temp.

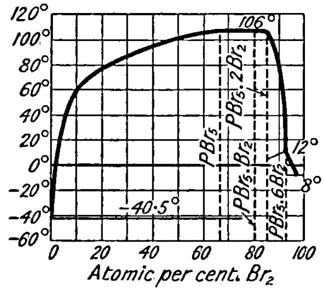

FIG. 50.—Thermal Diagram of the System: PBr_3–Br_2.

The properties of phosphorus pentabromide.—Phosphorus pentabromide at ordinary temp. is a lemon-yellow solid which A. J. Balard described as appearing in rhombohedral crystals after melting, and in needle-like crystals after sublimation. According to A. E. Nordenskjöld, the rhombic bipyramids have the axial ratios $a:b:c=0·6032:1:0·4010$. E. Baudrimont said that the crystals are red when the molten pentabromide is cooled slowly, and yellow, if cooled rapidly. H. Moissan made analogous observations. Consequently, it has been maintained that the yellow rhombic and the red prismatic varieties are allotropic forms of the pentabromide; but J. H. Kastle and W. A. Beatty explained the difference on the assumption that the red form is phosphorus heptabromide—*vide infra*—and the yellow form the pentabromide. The former in contact with water produces white phosphoryl bromide, and the latter passes into soln. without forming this product. E. B. R. Prideaux found the sp. and mol. vols. of liquid phosphorus pentabromide at 85° to be respectively 0·3530 and 152·1; at 100°, 0·3621 and 156·0; at 130°, 0·3755 and 161·7; and at 165°, 0·3899 and 168·0. The at. vol. of the contained phosphorus is greater with the bromide than with the chloride; and greater with tervalent than with quinquevalent phosphorus. There is a point of inflexion in the expansion curve at 100° corresponding with that of sulphur at 159°. The expansion from 85° to 100° is represented by $v=v_{85}(1+0·0019\theta)$, and from 100° to 165° by $v=v_{100}(1+0·0012\theta)$. Analyses by C. Löwig, H. Moissan, and T. E. Thorpe and A. E. H. Tutton agree with the formula PBr_5, and G. Oddo and M. Tealdi's observation on the lowering of the f.p. of phosphoryl chloride, and of benzene by the dissolved pentabromide agree with the simple mol. PBr_5. According to A. J. Balard, when the pentabromide is heated, it melts to a red liquid which, at a higher temp. gives off red vapours, and, added J. H. Gladstone, a mixture of phosphorus tribromide and bromine is formed at 100°, and the pentabromide is reformed on cooling. E. Baudrimont said that if carbon dioxide be passed into a bulb containing the pentabromide heated by a water-bath, bromine passes off and the tribromide remains. J. H. Kastle and W. A. Beatty said that the dissociation of the pentabromide dissolved in carbon disulphide or tetrachloride soon attains a limiting value. E. B. R. Prideaux gave 106° for the estimated b.p. at 760 mm. The observed vap. press., p mm., being:

	23°	41°	61°	75°	79°	88°	100°	106°
p . .	6	35	109	217	237	337	560	(760)

According to J. Ogier, the heat of formation of the solid pentabromide is $(P,5Br_{liq.})=63·5$ Cals.; $(P,5Br_{gas})=83·0$ Cals.; $(P,5Br_{solid})=63·3$ Cals.;

($PBr_3, Br_{2liq.}$)=20·3 Cals. P. Walden examined the electric conductivity of the pentabromide dissolved in liquid sulphur dioxide or arsenic trichloride. W. A. Plotnikoff observed that phosphorus pentabromide dissolved in bromine conducts an electric current, depositing phosphorus on the cathode, and combines with bromine to form pentabromide. W. Finkelstein measured the decomposition potential of the pentabromide in bromine, liquid sulphur dioxide, arsenic trichloride, and nitrobenzene.

A. J. Balard said that the pentabromide is not reduced by **hydrogen,** it fumes strongly in **air,** and deliquesces in humid air, forming, according to J. H. Gladstone, phosphoryl bromide. A. J. Balard recognized that the pentabromide is decomposed by **water,** forming phosphoric and hydrobromic acids. M. Trautz observed no signs of luminescence when hot or cold water reacts with phosphorus pentabromide. A. J. Balard showed that the pentabromide is decomposed by **chlorine,** forming bromine and phosphorus trichloride. W. Finkelstein observed that when soln. of phosphorus pentabromide in **bromine** are electrolyzed, the phosphorus moves towards the cathode. J. H. Gladstone showed that **iodine** reacts: $3PBr_5+I_2=3PBr_3+2IBr_3$. E. Baudrimont found that with **hydrogen sulphide** thiophosphoryl bromide is formed: $PBr_5+H_2S=PSBr_3+2HBr$; and F. Clausnitzer, that conc. **sulphuric acid** forms hydrogen bromide, bromine, sulphur dioxide, and sulphur bromide. A. Besson found that dry **ammonia** passed into a soln. of the pentabromide in carbon tetrachloride furnishes *phosphorus enneaamminotetrabromide*, $PBr_5.9NH_3$; and J. H. Gladstone, that with **phosphine** the first stage of the reaction is to be symbolized: $3PBr_5+PH_3=4PBr_3+3HBr$, and then $PBr_3+PH_3=2P+3HBr$. E. Berger observed that **phosphorus pentoxide** forms phosphoryl bromide. A. Michaelis found that **thiopyrophosphoryl bromide** is converted into thiophosphoryl bromide; and A. Geuther and A. Michaelis, that **pyrophosphoryl chloride** reacts: $P_2O_3Cl_4+PBr_5=2POCl_2Br+POBr_3$. E. Baudrimont found that **antimony trisulphide** reacts: $Sb_2S_3+3PBr_5=3PSBr_3+2SbBr_3$. G. Gustavson showed that **boric oxide** reacts with phosphorus pentabromide with difficulty, forming boron tribromide. J. Tarible added that a soln. of **boron tribromide** in carbon disulphide furnishes crystals of *boron phosphoctobromide*, $BBr_3.PBr_5$. The pentabromide reacts with **acetic acid**: $PBr_5+CH_3COOH=POBr_3+HBr+CH_3COBr$; and E. Baudrimont, with **oxalic acid**: $PBr_5+(COOH)_2=POBr_3+2HBr+CO+CO_2$. A. J. Balard observed that when heated in contact with the **metals,** phosphorus pentabromide usually forms the metal phosphide and bromide; with **gold,** L. Lindet obtained *auric phosphoctobromide*, $AuBr_3.PBr_3$. A. Rosenheim and W. Levy said that **platinum** reacts at 170°–200°, forming *platinous phosphopentabromide*, $PtBr_2.PBr_3$. M. F. Schurigen found that in a sealed tube at 310° **iridium** and **ruthenium** are attacked by phosphorus pentabromide, forming respectively *iridium phosphohexabromide*, $IrBr_3.PBr_3$, and *ruthenium pentaphosphoenneadecabromide*, $Ru_2(PBr_3)_5Br_4$. C. Löwig observed that **copper and mercury oxides** form bromides and phosphate; and E. Baudrimont with **lead oxide,** the reaction is attended by a glow of the mass.

Phosphorus heptabromide, PBr_7, was prepared by J. H. Kastle and W. A. Beatty by mixing equimolar proportions of bromine and phosphorus pentabromide in a sealed tube, and subliming at 90°. The product occurs as bright red, transparent crystals. The red form of phosphorus pentabromide is considered to be the heptabromide. Its formation by subliming the yellow pentabromide at 90° is said to be due to a partial decomposition into heptabromide and tribromide; phosphorus tribromide reconverts it into the yellow pentabromide. Bromine vapour converts the yellow pentabromide into the red compound, whilst when left in contact with bromine absorbents the reverse change takes place. In contact with water, phosphorus pentabromide gives a colourless soln. of phosphoric and hydrobromic acids, whilst the red compound liberates free bromine.

J. H. Gladstone found that when phosphorus pentabromide is oxidized by exposure to air it deliquesces, forming a red syrupy liquid of **phosphoryl bromide,**

$POBr_3$, or *phosphorus oxybromide ;* E. Berger oxidized the pentabromide by the pentoxide : $P_2O_5+3PBr_5=5POBr_3$; and, as indicated above, H. Ritter obtained it by the reaction of acetic acid on the pentabromide ; and E. Baudrimont, by the action of oxalic acid. A. Geuther and A. Michaelis also obtained it by the action of pyrophosphoryl chloride on the pentabromide : $PBr_5+P_2O_3Cl_4=POBr_3+2POBrCl_2$; and by treating phosphorus dibromotrichloride with water : $3PCl_3Br_2+3H_2O=2POCl_3+POBr_3+3HCl+3HBr$; or with acetic acid : $2PCl_3Br_2+3CH_3COOH=3CH_3COCl+POBr_3+POCl_3+HBr+H_2O$. Phosphoryl bromide is also produced by oxidizing phosphorus tribromide—*e.g.*, E. Demole, by the action of oxygen on the boiling tribromide ; and A. Geuther and A. Michaelis, by the action of nitrogen peroxide or trioxide on the well-cooled tribromide. A. Besson observed that phosphoryl bromide is produced when a mixture of the vapour of phosphoryl chloride and hydrogen bromide is passed through a tube at 400°–500°, and by the action of a soln. of bromine in carbon tetrachloride on phosphorus hemioxide. T. E. Thorpe and A. E. H. Tutton noted its formation by the action of bromine on phosphorous oxide : $P_4O_6+4Br_2=2POBr_3+2PO_2Br$.

E. Baudrimont described phosphoryl bromide as an orange mass consisting of thin, colourless plates ; H. Ritter also said that the crystals are colourless plates, with sp. gr. 2·822. Analyses by J. H. Gladstone, H. Ritter, and E. Baudrimont agree with the formula $POBr_3$; and the values of the vapour density 10·06, obtained by J. H. Gladstone, and 10·11, obtained by E. Berger, are close to 9·94 required for $POBr_3$. G. Oddo and co-workers found the mol. wt., calculated from the effect on the b.p. of chloroform, to be 298 ; on the b.p. of benzene, 344 ; and on the f.p. of benzene, 300. The value for $POBr_3$ is 287. H. Ritter gave for the m.p. 45°–46° ; E. Baudrimont, 35° ; A. Besson, 56° ; E. Berger, 55°–56° ; and T. E. Thorpe and A. E. H. Tutton, 45°. J. H. Gladstone said that the b.p. is between 170° and 200° ; H. Ritter gave 195° ; E. Baudrimont, 193° ; E. Berger, 189·5° at 774 mm. ; T. E. Thorpe and A. E. H. Tutton, 195° at 760 mm. ; and P. Walden, 193° at 758 mm. J. Ogier found the heat of formation of solid phosphoryl bromide from solid phosphorus to be $(P,O,3Br_{liq.})=108$ Cals., and E. Berger, 109·65 Cals. ; while J. Ogier gave $(P,O,3Br_{gas})=120$ Cals., and E. Berger, 120·75 Cals. E. Berger also found $(PBr_{3liq.},O)=64{\cdot}85$ Cals., and for the decomposition by water, 75 Cals. P. Walden said that the liquid is an electrical conductor, and suggested that it contains the tervalent ion $PO^{\cdots}$.

According to J. H. Gladstone, phosphoryl bromide is not miscible with **water,** but is decomposed by that reagent, forming phosphoric and hydrobromic acids ; it is decomposed by **chlorine** with the expulsion of bromine ; **bromine** forms yellow crystals which liquefy and decompose into bromine and phosphoryl bromide. E. Baudrimont found that **hydrogen sulphide** converts phosphoryl into thiophosphoryl bromide ; and A. Stock, that liquid hydrogen sulphide dissolves phosphoryl bromide, and on evaporating the soln. thiophosphoryl bromide remains, while if the soln. be allowed to remain for some time in contact with phosphorus pentoxide before it is evaporated, some phosphorus pentasulphide is formed. E. Baudrimont found that **phosphorus** does not attack heated phosphoryl bromide ; that **antimony** is brominated ; and that the products of the reaction with **antimony trichloride** are phosphoryl chloride, phosphorus sulphide and tribromide, and antimony tribromide and oxybromide. Ethyl bromide is produced by the action of **alcohol** on phosphoryl bromide. J. H. Gladstone said that **metals** are not attacked ; but, added E. Baudrimont, **tin** is brominated.

A. Michaelis did not succeed in making *pyrophosphoryl bromide,* $P_2O_3Br_4$, by the action of nitrogen peroxide or trioxide on phosphorus tribromide—the products are phosphorus pentoxide and phosphoryl bromide. T. E. Thorpe and A. E. H. Tutton said *metaphosphoryl bromide,* PO_2Br, is produced by the action of bromine on phosphorous oxide as indicated above, and it remains as a residue after the phosphoryl bromide has been removed by distillation.

§ 35. The Phosphorus Iodides and Oxyiodides

The observations of C. L. Gazzaniga,[1] A. Schrötter, and T. S. Traill were treated in connection with the action of iodine on phosphorus. Some indefinite iodides were mentioned by F. Wöhler, J. L. Gay Lussac, C. M. van Dijk, R. Boulouch, K. I. Lissenko, and F. Sestini. The two best defined iodides are the diiodide and triiodide ; while the existence of the tetritaiodide, the tetratritaiodide, and of the pentaiodide is not so well established. According to R. Boulouch, where dry iodine is added to a soln. of phosphorus in dry carbon disulphide in quantity less than is necessary to convert the phosphorus into the diiodide, and the mixture is exposed to sunlight, **phosphorus tetritaiodide,** P_4I, separates. This is an amorphous, red powder; it decomposes without melting, forming phosphorus diiodide (which dissociates) and phosphorus vapour, and is only slowly attacked by water. Dil. nitric acid attacks the tetritaiodide vigorously, liberating iodine, and with conc. nitric acid, it inflames. Conc. soln. of the alkali hydroxide dissolve it, liberating hydrogen phosphide, and dil. soln. of the alkali hydroxides or carbonates convert it into P_4OH. Phosphorus tetritaiodide dissolves in soln. of iodine, forming phosphorus diiodide or triiodide; this reaction serves to distinguish it from red phosphorus. A. Siemens considers that the alleged tetritiodide is nothing but red phosphorus contaminated with a little diiodide. A. Besson assumed the formation of *phosphorus tritatetraiodide*, P_3I_4, in the preparation of red phosphorus by the action of yellow phosphorus on a soln. of iodine in carbon tetrachloride. The hypothetical compound is supposed to decompose in light $P_3I_4=P_2I_4+P_{red}$.

J. L. Gay Lussac said that on bringing together one part of phosphorus and 16 parts of iodine, a grey-black crystallized substance, fusible at 29°, is formed, and producing on contact with water a colourless soln. containing hydriodic and phosphorous acids; while one part of phosphorus with 24 parts of iodine gave a black substance, fusible in part, at 46°, and dissolving in water with elevation of temp., the soln. containing hydriodic and phosphoric acids, and exhibiting a dark brown colour from the presence of free iodine. F. Hampton said that there is evidence of the formation of **phosphorus pentaiodide,** PI_5, when the two elements are brought together in an atm. of nitrogen; but it is difficult to regulate the violence of the reaction; but if carbon disulphide is used as a solvent for the phosphorus before adding iodine, the process is more manageable.

The formation and preparation of phosphorus diiodide.—J. L. Gay Lussac,[2] and C. A. Wurtz obtained phosphorus diiodide, PI_2, or P_2I_4, by fusing together eq. proportions of the constituent elements. H. W. Doughty recommended heating a mixture of 50 grms. of iodine and 4 grms. of red phosphorus in a 250 c.c. flask by a free flame until the contents are melted; and when the mixture has cooled to 60°, adding 2·5 grms. of yellow phosphorus in small pieces at a time. The process is said to be quick and safe. B. Corenwinder made the diiodide by adding an eq. proportion of iodine to a soln. of phosphorus in carbon disulphide. On cooling the liquid to 0°, crystals of the diiodide separate. They are then exposed to a current of dry air to remove the solvent. Modifications of this process were used by B. Franke, M. Berthelot and S. de Luca, and A. Michaelis and M. Pitsch. The process was also recommended by A. Besson, and R. N. Traxler and F. E. E. Germann. H. Ritter obtained the diiodide by the action of a soln. of iodine in acetic acid on phosphorus trichloride; V. Auger and M. Billy, by the action of phosphorus trichloride on magnesium methyliodide: $3PCl_3+4Mg(CH_3)I=P_2I_4+P(CH_3)_4Cl+4MgCl_2$; A. Besson, by reducing a soln. of phosphorus triiodide in carbon disulphide by mercury; A. W. Hofmann, by the action of iodine on phosphine: $8PH_3+5I_2=P_2I_4+6PH_4I$; A. Damoiseau, by the action of hydrogen iodide on ordinary phosphorus; or by allowing phosphorus to stand in contact with conc. hydriodic acid; P. de Wilde, by the action of phosphorus trichloride on phosphonium iodide; A. Besson, by the action of carbonyl chloride or phosphoryl chloride on phosphonium iodide: $4PH_4I+8COCl_2=P_2I_4+8CO+2P+16HCl$; E. and P. Fireman, by the action of phosphorus pentachloride on phosphonium iodide at 135°; T. E. Thorpe and A. E. H. Tutton, by the action of iodine on phosphorous oxide: $5P_4O_6+8I_2=4P_2I_4+6P_2O_5$; A. Besson, by the action of iodine on phosphorus hemioxide in the presence of carbon tetrachloride; and R. Boulouch, by the action of a soln. of iodine on phosphorus tetritaiodide; or by heating the tetritaiodide: $4P_4I=14P+P_2I_4$.

The properties of phosphorus diiodide.—The pale orange-coloured, triclinic crystals were found by A. E. Nordenskjöld to have the axial ratios $a:b:c=1·0365:1:0·6362$, and $\alpha=97° 54'$, $\beta=106° 25'$, and $\gamma=80° 30'$. E. Bamberger and J. Philipp said that the crystals are probably not isomorphous with those of arsenic diiodide. Analyses made by H. Ritter, and B. Corenwinder agree with the formula PI_2, but the vap. density determinations of L. Troost agree with the formula P_2I_4, since at 265° and 59–99 mm. press., he obtained a vap. density between 18·0 and 20·2—theory for P_2O_4 requires 19·4. L. Troost found that in an atm. of nitrogen under diminished press. the diiodide is not decomposed at 265°; but A. Besson said that some decomposition occurs during fusion, and at 100°–120° and 15 mm. press., the sublimate consists of phosphorus triiodide, and there is a residue of red phosphorus. There is therefore some uncertainty in the mol. wt. deduced from the vap. density. The m.p. given by B. Corenwinder, A. Besson, A. Michaelis and M. Pitsch, and E. and P. Fireman is 110°; and J. L. Gay Lussac gave 100°. R. N. Traxler and F. E. E. Germann gave 124·5°, and added that when a little sulphur is present, the m.p. is lowered. J. Ogier found the heat of formation of the solid diiodide from solid phosphorus to be $(P,I_{2solid})=9{\cdot}88$ Cals., and $(P,I_{2gas})=20{\cdot}68$ Cals.

B. Corenwinder noticed that the diiodide is decomposed by **water** into red phosphorus, some phosphine, and hydriodic and phosphorous acids; and A. Gautier said that if water be gradually added to the diiodide the reaction can be symbolized: $P_2I_4+5H_2O=4HI+H_3PO_3+H_3PO_2$, and the soln. remains clear; and with a large proportion of water there is formed a yellow precipitate with the composition P_5H_3O—*vide supra*. K. I. Lissenko, A. Michaelis and M. Pitsch, and A. Stock and co-workers consider A. Gautier's product to be impure hydrogen diphosphide. U. Antony and G. Magri found that 100 parts of liquid **hydrogen sulphide** dissolve 0·09 part of the diiodide with an absorption of heat and the production of a yellow soln. which conducts electricity. Dry hydrogen sulphide does not act on the diiodide at ordinary temp., but L. Ouvrard represented the reaction at 100°: $2P_2I_4+3H_2S=P_4S_3I_2+6HI$; he also represented the reaction with **phosphorus trisulphide**: $P_2S_3+P_2I_4=P_4S_3I_2+I_2$. J. Tarible found that with **boron tribromide**, the complex *phosphorus borotribromodiiodide*, $P_2I_4.2BBr_3$, or $PI_2.BBr_3$, is formed; while G. Gustavson observed that the diiodide does not react with **boron trioxide**. B. Corenwinder said that the diiodide is soluble in **carbon disulphide**. V. Auger showed that **magnesium methyl iodide** reacts with the diiodide, forming tetramethylphosphonium iodide; and **methyl, ethyl, or propyl iodide,** form iodides of the alkyl phosphines. V. Dessaignes found that **tartaric acid** and water react with the diiodide at 100°, forming malic acid and then succinic acid, but over 120°, gaseous products are obtained. A. Granger found that when the diiodide is heated to 275°–300° in a sealed tube with **mercury,** or when the vapour of the diiodide is passed over mercury at 250°, or when the diiodide is treated with mercury, normal mercuric phosphide is produced. A. Gautier showed that the diiodide reacts with **silver chloride** at ordinary temp.: $6AgCl+3PI_2=3PCl_3+6AgI$; and A. Besson represented the reaction with **mercurous chloride** by a similar equation.

The formation and preparation of phosphorus triiodide.—F. Sestini, R. N. Traxler and F. E. E. Germann, and B. Corenwinder prepared **phosphorus triiodide,** PI_3, adding 12 parts of iodine to a soln. of one part of phosphorus in carbon disulphide, evaporating the liquid out of contact with air, and cooling the syrupy liquid by means of a freezing mixture of ice and salt. The red crystalline plates can be freed from the solvent by a current of air at 50°–60°. L. Ouvrard used this process. A. Besson said that the ready solubility of the triiodide in this solvent makes the process an unfavourable one, and the product has not a high degree of purity. P. Hautefeuille prepared the triiodide by the action of dry hydrogen iodide on dry phosphorus trichloride at ordinary temp., and A. Besson recommended this process, using hydrogen iodide and phosphorus trichloride alone or in the presence of carbon tetrachloride as a solvent. H. L. Snape made the triiodide by heating dry phosphorus trichloride and potassium iodide—with oxygen excluded—in a sealed tube; A. Besson, by the action of hydrogen iodide on phosphoryl choride; L. Ouvrard, by heating the thiophosphoryl iodide: $3P_2SI_4=P_2S_3+4PI_3$; A. Besson, by the action of hydrogen iodide on thiophosphoryl chloride: $PSCl_3+5HI=PI_3+I_2+H_2S+3HCl$, by the action of iodine dissolved in carbon tetrachloride on phosphorus hemioxide, and as a sublimate by heating the diiodide under reduced press.—*vide supra;* R. Boulouch, by the action of a soln. of iodine on phosphorus tetritaiodide; and E. and P. Fireman, by heating phosphorus pentachloride with phosphonium iodide: $3PCl_5+3PH_4I=PI_3+PCl_3+12HCl+4P$.

The properties of phosphorus triiodide.—The deep red tabular or columnar crystals were found by A. E. Nordenskjöld to belong to the hexagonal system and to have the axial ratio $a:b=1:1{\cdot}1009$. The analyses by B. Corenwinder, and A. Besson, and the vap. density determination by L. Troost, agree with the formula PI_3. The vap. density at 250° under diminished press. was 14·32–14·61 when the theoretical value was 14·29. F. M. Jäger gave for the surface tension of the molten triiodide 56·5 dynes per cm. at 75·3°; 55·5 at 99·9°; 53·6 at 121·4°; and 51·4 at 150°. B. Corenwinder, L. Ouvrard, F. M. Jäger, and H. L. Snape gave 55° for the m.p.; and A. Besson, and R. N. Traxler and F. E. E. Germann, 61°. By the application of some arbitrary assumptions of F. M. Flawitzky, A. M. Wasiléeff inferred that the triiodide is a eutectic of the diiodide and iodine. B. Corenwinder said that the triiodide boils with the escape of iodine; and L. Ouvrard found that decomposition occurs when the compound volatilizes. A. Besson, however, said that the compound can be sublimed between 100° and 120° at 15 mm. press., but at a higher temp., iodine is set free. M. Berthelot found that the heat of formation of the solid triiodide from solid phosphorus is $(P,3I_{gas})=26{\cdot}7$ Cals.; $(P,3I_{solid})=10{\cdot}5$ Cals.; and J. Ogier gave $(P,3I)=10{\cdot}9$ Cals. H. Schlundt found the dielectric constant of the solid triiodide to be 3·66 at 20°; and for the liquid, 4·12 at 65°.

B. Corenwinder said that phosphorus triiodide is decomposed by moist **air,** and, added L. Ouvrard, this more easily than is the case with the diiodide. B. Corenwinder found that the triiodide reacts with **water,** forming hydriodic and phosphorous acids and a yellow solid; and A. Besson also found that iodine or some other solid separates out. J. H. Gladstone found that the triiodide is converted by **chlorine** into the trichloride. R. Hanslian discussed the mol. wt. from the effect on the f.p. and b.p. of **iodine.** With a soln. of **sulphur** in carbon disulphide, T. Karantassis observed the formation of **phosphorus tetracosithiotriiodide,** $PI_3.3S_8$. L. Ouvrard represented the reaction with dry **hydrogen sulphide** on the molten triiodide by the equation: $2PI_3+2H_2S=4HI+P_2S_2I_2$; and at 150°, by $2PI_3+3H_2S=P_2S_3+6HI$. C. Hugot observed that the reaction with liquid **ammonia** above −65° agrees with: $PI_3+15NH_3=P(NH_2)_3+3NH_4(NH_3)_3I$; and the triamide is slowly resolved into the imide, $P_2(NH)_3$. L. Ouvrard represented the reaction with **phosphorus trisulphide**; $2P_2S_3+2PI_3=3P_2S_2I_2$, and with an excess of the triiodide: $P_2S_3+4PI_3=3P_2SI_4$. T. Karantassis found that phosphorus triiodide undergoes double decomposition with **arsenic trichloride, antimony tri- and penta-chlorides, bismuth chloride, stannic chloride,** and **lead chloride,** but the corresponding reverse reactions do not occur. No reaction was observed between phosphorus triiodide and **silicon or zirconium tetrachloride.** It is concluded that the iodides of the tervalent metalloids of low at. wt. undergo double decomposition with the bromides or chlorides of higher at. wt. G. Gustavson observed no reaction with **boron trioxide**; and J. Tarible found that with **boron tribromide,** the triiodide forms *phosphorus borotribromodiiodide,* $2PI_3+2BBr_3=P_2I_4.2BBr_3+I_2$. The triiodide was found by A. Besson, and L. Ouvrard to be readily soluble in **carbon disulphide.** J. W. Walker and F. M. G. Johnson represented the reaction with **methyl, ethyl, or n-propyl alcohol** by an equation of the type: $PI_3+3C_2H_5OH=2C_2H_5I+HI+P(OH)_2(OC_2H_5)$. A. Besson said that a soln. of the triiodide in carbon disulphide is reduced by **mercury** in the cold, forming the diiodide, and if the mercury is in excess, mercurous iodide and mercury iodophosphide are formed. J. H. Gladstone added that when the triiodide is distilled with **mercuric chloride,** phosphorus trichloride is formed.

P. Lemoult obtained **phosphorus trisiodomercuriate,** $P(HgI)_3$, by the action of phosphine, diluted with hydrogen or carbon dioxide, on a dil. soln. of potassium iodomercuriate. The product is washed and dried in vacuo. It is slowly decomposed by warm water; and rapidly by alkali-lye. Nitric acid and aqua regia decompose it violently. F. Venturoli prepared yellow **phosphorus iodobisiodomercuriate,** $I.P:(HgI)_2$, by the action of phosphorus on an alcoholic soln. of potassium iodide. The product is decomposed by heat into phosphorus, and mercurous and mercuric iodides.

The phosphorus oxyiodides.—A. Besson suggested that a small quantity of a phosphorus oxyiodide is formed when hydrogen iodide acts on phosphoryl chloride because the resulting phosphorus triiodide gives a relatively small quantity of yellow crystalline plates when decomposed by cold water. According to S. Burton, an oxyiodide with the composition $P_3I_6O_8$ is found in the residue left in the retort in the preparation of ethyl iodide, and may be separated by treating the residue with water, filtering, and evaporating, whereupon it is deposited in red granular crystals, which may be purified by recrystallization. It dissolves readily in water, alcohol, and ether, forming colourless soln. It melts at 140°, and at a higher temp. gives off yellowish vapours, which turn starch-iodide test-paper blue, and condense on a cold surface as a yellowish-red crystalline deposit, exhibiting all the characters of the original substance, which therefore partly sublimes unaltered. Another oxyiodide with the composition PI_2O_2, or $P_4I_8O_8$, was observed in the residue from the preparation of fuming hydriodic acid, and also in the residue from the preparation of methyl iodide.

§ 36. The Mixed Halides and Oxyhalides of Phosphorus

A number of mixed halides of phosphorus have been reported. H. Moissan[1] observed that phosphorus trifluoride unites additively with chlorine, forming the mixed pentahalide, **phosphorus trifluodichloride,** PF_3Cl_2; and C. Poulenc recommended the following mode of preparation. Two half-litre flasks, provided with leading tubes from the upper and lower parts, and filled with chlorine and phosphorus trifluoride respectively, are connected in such manner that the fluoride can be displaced by mercury into the upper part of the chlorine flask. The gases contract to half their original volume, in accord with the equation $PF_3+Cl_2=PF_3Cl_2$, so that the operation is complete when the whole of the fluoride has been transferred. The mixture is left alone for some days; it must not be shaken with mercury, as it is slowly attacked by it even in the cold. The trifluodichloride is a colourless, non-inflammable gas with a sharp, irritating odour. Its vap. density, 5·39–5·42, is in agreement with 5·46 calculated for PF_3Cl_2. It liquefies under ordinary press. at —8°; and it is decomposed by heating it to 200°–250°, or by the passage of electric sparks: $5PF_3Cl_2=3PF_5+2PCl_5$. With hydrogen, at 250°, it forms phosphorus trifluoride and hydrogen chloride. A small proportion of water decomposed it: $PF_3Cl_2+H_2O=POF_3+2HCl$; and with a larger proportion, the oxyfluoride is decomposed: $POF_3+3H_2O=H_3PO_4+3HF$. It is instantly absorbed and decomposed by alkali-lye. It reacts with sulphur at 115°, forming sulphur monochloride and thiophosphoryl fluoride (*q.v.*). When ammonia is brought in contact with the gas, a white cloud appears and condenses on the walls of the containing vessel—it is phosphorus trifluodiamide; with phosphorus at 120°. This compound is decomposed, forming phosphorus trifluoride and trichloride. Absolute alcohol absorbs the gas, forming a liquid which is a mixture of ethyl chloride and fluoride and some phosphorous acid. The gas is completely absorbed by sodium; while magnesium, mercury, aluminium, tin, lead, iron, and nickel attack it at 180°, forming the metal chlorides, and liberating phosphorus trifluoride.

H. Moissan found that bromine rapidly absorbs phosphorus trifluoride, and if the trifluoride be in excess, the liquid is almost decolorized and **phosphorus trifluodibromide,** PF_3Br_2, is produced. In preparing this compound, the bromine should be cooled by a freezing mixture. Phosphorus trifluobromide is a pale brown, mobile liquid which fumes strongly in air, attacking the respiratory organs. The liquid freezes to a pale yellow crystalline solid at —20°, which melts immediately the freezing mixture is removed. When the liquid is kept at about 15° it soon begins to decompose, giving off bubbles of gas and forming crystals of phosphorus pentabromide: $5PF_3Br_2=3PF_5+2PBr_5$. The compound is vigorously decomposed by water: $PF_3Br_2+4H_2O=H_3PO_4+3HF+2HBr$. It does not attack glass. H. Moissan also found that iodine absorbs phosphorus trifluoride, forming at 300°–400° a yellowish-red solid—possibly **phosphorus trifluodiiodide,** PF_3I_2. The glass containing vessel is at the same time attacked.

The action of bromine on phosphorus trichloride was first investigated by J. H. Gladstone[2] in an attempt to prepare a chlorobromide. He found that when bromine was poured into phosphorus trichloride, it sank to the bottom and two layers were formed, the upper consisting of a soln. of bromine in the trichloride and the lower of a soln. of the trichloride in bromine. These two layers could not be made to mix, but on adding a little iodine combination immediately took place with development of much heat, and, on cooling, red, crystalline masses separated, resembling phosphorus pentabromide with excess of bromine. The reaction was probably $PCl_3+Br_5I=PBr_5+ICl_3$. He tried other methods for preparing the complex compound, but without success. H. Wichelhaus said that phosphorus trichloride and bromine unite with the development of heat, and the well-cooled mixture deposits crystals of **phosphorus trichlorodibromide,** PCl_3Br_2, but at ordinary temp., the liquid separates into two layers. C. Friedel and A. Ladenburg found an equimolar mixture of phosphorus trichloride and bromine behaved as if it were a trichlorodibromide. A. Michaelis prepared the trichlorodibromide by keeping an eq. mixture of the trichloride and bromine in a sealed tube at a winter's temp. for some time ; the compound decomposed into its components at 35°. A. L. Stern also showed that the trichlorobromide is the first product of the action of the trichloride on bromine.

A. Michaelis said that the trichlorodibromide has the appearance of phosphorus pentabromide. It decomposes about 35° into phosphorus trichloride and bromine, and these components re-unite at a lower temp. The compound is decomposed by water ; H. Wichelaus represented the reaction : $PCl_3Br_2+H_2O=PCl_3+HOBr+HBr$; followed by $HOBr+PCl_3=HCl+POBrCl_2$; while A. Geuther and A. Michaelis represented the reaction by $3PCl_3Br_2+3H_2O=2POCl_3+POBr_3+3HCl+3HBr$. A. Michaelis found that with a soln. of bromine in phosphorus trichloride, it forms trichlorotetrabromide ; and when treated with sulphur dioxide, $PCl_3Br_2+SO_2=POCl_3+SOBr_2$, followed by $2SOBr_2=SO_2+SBr_4$. When the product of the reaction is distilled, bromine and phosphoryl chloride pass over, and a black product, probably sulphur monobromide, remains. G. Gustavson found that with boric oxide boron trichloride and bromine are formed as in the case of phosphorus pentachloride ; H. Wichelhaus, and C. Friedel and A. Ladenburg found that the trichlorodibromide reacts like the pentachloride towards hydroxylic organic compounds ; and A. Geuther represented the reaction with acetic acid : $3PCl_3Br_2+3CH_3COOH=3CH_3COCl+POBr_3+2POCl_3+3HBr$. H. Wichelhaus regarded the trichlorodibromide as a molecular compound of phosphorus trichloride and bromine, but this does not harmonize well with the thermal decomposition $5PCl_3Br_2=3PCl_5+2PBr_5$; and, as pointed out by A. Michaelis, its reactions do not agree with the assumption that it is a mixture of phosphorus pentachloride and pentabromide.

A. L. Stern concluded from his study of the action of bromine on phosphorus trichloride that when bromine is added to phosphorus trichloride, two atoms of bromine may be made to unite with one mol of the chloride, forming the chlorobromide ; when more bromine is added one atom of chlorine in this is displaced by bromine, forming **phosphorus dichlorotribromide,** PCl_2Br_3 ; and still more bromine being added, this compound unites with part of it, forming phosphorus dichloropentabromide, PCl_2Br_5, and at a lower temp. with still more bromine. The number of atoms of halogen with which one atom of phosphorus can combine depends on the temp. : thus phosphorus in presence of 15 gram-atoms of halogen at temp. 13°–15° can combine with only 7 atoms, whereas phosphorus in the presence of 11 gram-atoms of halogen united with 10 gram-atoms to form a compound dissociating above 10°. All the chlorine in the trichloride cannot be displaced by the unaided action of bromine, even if such a large excess as 12 gram-atoms of bromine to 1 mol of phosphorus trichloride be allowed to react for a month ; the presence of a small quantity of iodine, however, will enable a much larger quantity of the chlorine to be displaced.

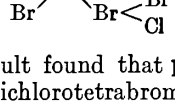
M. Prinvault reported that yellow crystals of **phosphorus tetrachlorobromide,** PCl_4Br, separate when a cold soln. of the dibromoheptabromide in phosphorus trichloride is heated to its b.p. ; and this compound is also formed by the action of bromine chloride on phosphorus trichloride. He said that the yellow crystals can be regarded as a mol. compound $PCl_3.BrCl$. While the three bromochlorides, PCl_4Br, PCl_3Br_2, and PCl_2Br_3, can be regarded as substitution derivatives of phosphorus pentachloride, or pentabromide. Compounds corresponding with the heptahalide—for example, **phosphorus dichloropentabromide,** PCl_2Br_5, prepared by A. L. Stern, *vide supra ;* and PCl_3Br_4, *vide infra ;* with the unknown enneahalide, *e.g.* PCl_2Br_7 ; with the unknown henahalide, *e.g.* PCl_3Br_8—have been reported.

The *phosphorus trichloropentabromide*, PCl_3Br_5, of A. Michaelis is very doubtful. It was said to be formed by adding bromine to an excess of phosphorus trichloride. It may be a supersaturated soln. of ordinary trichlorodibromide in bromine; when the trichlorodibromide is added to the alleged compound, **phosphorus trichlorotetrabromide,** PCl_3Br_4, is produced. A. Michaelis obtained the trichlorotetrabromide by adding bromine to an excess of phosphorus trichloride, and seeding the liquid with a crystal of the desired compound; he also found that in a mixture of phosphorus trichloride and bromine, the lower layer immediately solidified, the trichlorotetrabromide separated out, just as a supersaturated soln. solidifies when a crystal of the salt is dropped into it. M. Prinvault obtained this compound by allowing a mixture of equimolar parts of phosphorus trichloride and trichloroctobromide to stand for some days in a sealed tube. He represented the reaction: $PCl_3Br_8+PCl_3=2PCl_3Br_4$; he also obtained it by dissolving the dichloroheptabromide and then the trichloroctobromide in phosphorus trichloride, and allowing the soln. to stand for some days; and also by the reaction: $PCl_4Br+PCl_2Br_7=2PCl_3Br_4$. The ruby-red prismatic crystals of the trichlorotetrabromide have a blue lustre. The crystals were found by A. Michaelis to be always contaminated with adsorbed bromine, or phosphorus trichloride. The formula agrees with the analyses of A. Michaelis, and M. Prinvault. The former regarded these chlorobromides as mol. compounds of phosphorus trichloride and bromine monochloride. As A. L. Stern pointed out, A. Michaelis' hypothesis is untenable in view of the displacement of the chlorine of the trichloride by bromine; A. Geuther represented the at. structure of the trichlorotetrabromide by

$$\begin{matrix}Cl_2\\Br_2\end{matrix}\!\geqslant\! P-Br\!<\!\begin{matrix}Br\\Cl\end{matrix}$$

M. Prinvault found that the trichlorotetrabromide decomposes at 60° when heated in a sealed tube: $2PCl_3Br_4=PCl_3+PCl_3Br_8$; when the tube is cooled, the reaction is reversed in a few days' time. A. Michaelis said that the crystals melt when heated, forming two liquid layers which re-unite on cooling to form crystals of the original salt. The compound is decomposed by a small proportion of water into phosphoryl chloride and bromide, hydrochloric and hydrobromic acids, and free bromine; and by a large proportion of water into phosphoric, hydrochloric, and hydrobromic acids and free bromine as recorded by M. Prinvault. A. Michaelis showed that the compound is not altered when shaken with phosphorus trichloride, and it reacts with sulphur dioxide: $2PCl_3Br_4+SO_2=2POCl_3+SBr_4+2Br_2$.

According to M. Prinvault, when phosphorus trichloroctobromide is rapidly distilled above 90°, crystals of **phosphorus dichloroheptabromide,** PCl_2Br_7, appear in the receiver. It was also formed by adding phosphorus trichloride to bromine; there is a vigorous reaction, and after some time, the mixed liquids deposit crystals of this compound. The crystals are said to be very unstable; and to be decomposed by dry air, by carbon disulphide, and by warming them—phosphorus pentabromide and bromine monochloride are formed. The compound dissolves in phosphorus trichloride, and when the soln. is heated to its b.p., phosphorus tetrachlorobromide is formed as indicated above. The dichloroheptabromide is decomposed by water into bromine, and phosphoric, hydrochloric, and hydrobromic acids. M. Prinvault considered it to be a mol. compound $PBr_5.2BrCl$; but A. L. Stern said that M. Prinvault's hypothesis is untenable because compounds are known with less than 5 atoms of bromine to one of phosphorus. A. Geuther supposed that it has the atomic structure



As just indicated, M. Prinvault found that **phosphorus trichloroctobromide,** PCl_3Br_8, is produced when the trichlorotetrabromide is heated in a sealed tube to

60°. He also found that when the homogeneous liquid obtained by adding bromine to phosphorus trichloride is heated on a water-bath at 65° until bromine is no longer evolved, the red liquid which remains forms brown needles at —4° to —5°. A. Michaelis heated a mixture of two mols of bromine with one mol of phosphorus trichloride, and obtained an oily liquid which, on cooling, furnished brown needles with a green reflex. Analyses of the brown acicular crystals agree with the above formula. A. Michaelis found that the compound melts at about 25°, re-forming the original salt on cooling. M. Prinvault said that the compound can be distilled below 90° without decomposition, but above that temp. it forms dichloroheptabromide; while A. Michaelis said that the compound cannot be distilled without decomposition, and that the vapour has the colour of free bromine. M. Prinvault observed that water decomposes the compound into bromine, and phosphoric, hydrochloric, and hydrobromic acids; A. Michaelis found that at ordinary temp. the trichloroctobromide reacts very slowly with sulphur dioxide, but when heated on a water-bath, bromine, phosphoryl chloride, and sulphur bromide are rapidly formed. M. Prinvault said that the compound is soluble in carbon disulphide, and sparingly soluble in phosphorus trichloride with which it forms phosphorus trichlorotetrabromide; A. Michaelis made some observations on this subject—*vide supra*, phosphorus trichloropentabromide. M. Prinvault regarded this substance as a mol. compound of PBr_4 and 3BrCl; and A. Michaelis as a mol. compound of $PCl_3Br_2.3Br_2$. A. Geuther regarded this compound as having the structure:

$$\begin{matrix}\text{Br}\\\text{Br}\end{matrix}\!>\!\text{P}\equiv\left(\text{Br}<\begin{matrix}\text{Cl}\\\text{Br}\end{matrix}\right)_3$$

C. G. Moot[3] reported what was probably **phosphorus trichlorodiiodide,** PCl_3I_2, though the analysis corresponded with PCl_3I. It was obtained by adding an excess of iodine to phosphorus trichloride, and allowing the mixture to stand a few days. The crystals were dried in a current of air, and recrystallized from carbon disulphide. The red, six-sided crystals are decomposed by moist air, and they are very hygroscopic. They decompose at 259° with the separation of iodine. E. Baudrimont prepared **phosphorus hexachloroiodide,** PCl_6I, or $PCl_5.ICl$, by the action of iodine mono- or tri-chloride on phosphorus pentachloride: $PCl_5+ICl_3=PCl_5.ICl+Cl_2$; by direct addition of iodine trichloride and phosphorus trichloride; and by the action of iodine on phosphorus pentachloride: $3PCl_5+I_2=2PCl_6I+PCl_3$. The compound sublimes at about 200°, furnishing orange-red needles or plates. Its vap. density is 4·993 at 260° when the theoretical value for the undecomposed compound is 12·8 and for the compound, when dissociated: $PCl_5.ICl=ICl+Cl_2+PCl_3$, it is 4·27. The compound fumes in moist air, and deliquesces rapidly; it is decomposed by water: $PCl_5ICl+4H_2O=H_3PO_4+5HCl+ICl$.

A series of phosphoryl chlorobromides has been reported, including, with the terminal members, $POCl_3$, $POCl_2Br$, $POClBr_2$, and $POBr_3$. N. Menschutkin[4] reported **phosphoryl dichlorobromide,** $POCl_2Br$, to be formed by treating phosphoryl ethylchloride, $PO(C_2H_5)Cl_2$, with bromine drop by drop. The more volatile ethyl bromide so produced can be separated by fractional distillation from the phosphoryl dichlorobromide—phosphoryl ethylchloride is produced by the action of phosphorus trichloride on alcohol. Other phosphoryl alkylchlorides gave a similar product. According to H. Wichelhaus, phosphoryl dichlorobromide is produced by the action of bromine on a mixture of benzoic acid and phosphorus trichloride when phosphorus trichlorodibromide is first formed: $PCl_3Br_2+C_6H_5.COOH=POCl_2Br+HBr+C_6H_5COCl$; but A. Geuther and A. Michaelis, and K. Kraut did not succeed in confirming this result, and they represented the reaction $3PCl_3Br_2+3C_6H_5COOH=2POCl_3+POBr_3+3C_6H_5COCl+3HBr$ as in the analogous case with water—*vide supra*. A. Besson said that the dichlorobromide is formed when the chlorodibromide is heated to its b.p.: $2POClBr_2=POCl_2Br+POBr_3$; and when a mixture of hydrogen bromide and the vapour of phosphoryl chloride is passed through a glass tube at 400°–500°; at the same time there are formed phosphoryl chlorodibromide, and bromide. These can be separated by fractional distillation. A. Geuther and A. Michaelis obtained it by the action of phosphorus pentabromide on pyrophosphoryl chloride: $PBr_5+P_2O_3Cl_4=2POBrCl_2+POBr_3$; and A. Geuther and O. Hergt, by the action of the pentabromide on phosphorus ethoxydichloride: $P(OC_2H_5)Cl_2+PBr_5=POCl_2Br+PBr_3+C_2H_5Br$, or on phosphoryl ethoxydichloride; $PO(OC_2H_5)Cl_2+PBr_5=POCl_2Br+POBr_3+C_2H_5Br$. Analyses by N. Menschutkin, and H. Wichelhaus agree with the above formula; and N. Menschutkin's value 7·52 for the vap. density agrees with the value 6·86 calculated for $POCl_2Br$. Phosphoryl dichlorobromide is a pale yellow, refracting liquid which, according to A. Geuther and A. Michaelis, freezes to colourless, tabular crystals at 0°, and the solid melts at 11°. A. Besson gave 13° for the m.p., and added that the liquid is very readily undercooled, and that crystallization is then induced by seeding with the dichlorobromide or the chlorodibromide. N. Menschutkin gave 2·059 for the sp. gr. at 0°; T. E. Thorpe, 2·12065 at 0°, and 1·83844 at 137·6° and the mol. vol. at the b.p. is 107·38. If the vol. at 0° is unity, that at the b.p. is 1·15894. He represented the vol., v, at $\theta°$, by $v=1+0·001005180\theta+0·0_6490530\theta^2+0·0_4440650\theta^3$. N. Menschutkin gave 137° for the b.p.; A. Besson, 135°–138°; and T. E. Thorpe, 137·6°. O. Masson, and J. A. Groshans studied the mol. vols. of the family of halides. E. Chambon, and A. Besson found that when fractionally distilled, or when heated in a sealed tube at 185°, phosphoryl dichlorobromide is decomposed into phosphoryl chloride and bromide. N. Menschutkin showed the dichlorobromide is decomposed by water, forming phosphoric acid; and E. Chambon, that phosphorous acid yields a mixture of hydrochloric, metaphosphoric, and orthophosphoric acids.

As indicated above, A. Besson obtained **phosphoryl chlorodibromide**, $POClBr_2$, by fractional distillation from the products of the action of dry hydrogen bromide on the vapour of phosphoryl chloride at 400°–500°. The solid melts at 30°; boils at 165°; and the sp. gr. at 50° is 2·45. As in the case of the dichlorobromide, it shows a great tendency to undercooling, and crystallization can then be induced by seeding with the dichlorobromide or the chlorodibromide. The compound fumes in air, and is at the same time slowly decomposed; with water it forms a mixture of phosphoric, hydrochloric, and hydrobromic acids. When the liquid is boiled in contact with air, the bromine is partially displaced by oxygen, and the product contains phosphoryl chloride, bromide, and dichlorobromide. When heated in a sealed tube, the reactions are: $2POClBr_2=POCl_2Br+POBr_3$; and $3POClBr_2=POCl_3+2POBr_3$.

§ 37. The Phosphorus Sulphides

The history of the compounds of phosphorus and sulphur is truly a comedy of errors. Compounds diligently investigated and carefully described by one worker could not be prepared by another worker or else are represented as mixtures.—B. HERSCOVICI.

A. S. Marggraf[1] recognized that the reaction of sulphur with phosphorus is very vigorous at an elevated temp., indeed, when a mixture of the dried elements is heated in a test-tube so much heat is evolved that an explosion may occur. At a lower temp. the fused elements mix in all proportions. Before any test was available as to the individuality of those products quite a large number of phosphorus sulphides was reported by B. Pelletier, M. Faraday, A. Dupré, A. Levol, R. Böttger, J. J. Berzelius, G. Lemoine, etc. These include P_4S, P_4S_2, P_4S_3, PS, P_4S_5, P_8S_{11}, P_2S_3, P_3S_5, P_4S_7, P_3S_6, P_4S_9, P_2S_5, P_2S_6, and P_2S_{12}. J. J. Berzelius, guided largely by the analogy between sulphur and oxygen, said that "phosphorus forms with sulphur a series of compounds precisely analogous in composition to those it forms with oxygen. Moreover, some of these compounds may be obtained in two allotropic forms in one of which the phosphorus appears to exist in its ordinary state, in the other, in its red modifications."

J. J. Berzelius described the preparation of *phosphorus tetritasulphide*, P_4S, by melting eq. proportions of the two elements under water, or on a water-bath ; W. Wicke said that the union may be effected at ordinary temp. A red modification was said to be obtained when the ordinary form, or the hemisulphide, is heated in contact with an electropositive metal sulphide—say sodium sulphide. J. J. Berzelius also described yellow and red forms of *phosphorus hemisulphide*, P_2S, or P_4S_2, obtained in a similar way by using eq. proportions of the two elements. According to H. Schulze, G. Ramme, A. Helff, and F. Isambert, these *hyposulphides* are mixtures of sulphur with red or yellow phosphorus, though G. Lemoine was inclined to regard them as chemical individuals. R. Boulouch reported *phosphorus tetritapentasulphide*, P_4S_5, to be formed by adding a crystal of iodine to a mixed soln. of sulphur (5–7 grms.), and the tetritatrisulphide (23 grms.) in carbon disulphide (200 c.c.). The crystals which separate in a couple of days retain the solvent very tenaciously, and melt at 180°–210°. He added that the sulphide is probably a solid soln. E. Dervin also reported *phosphorus octitahenasulphide*, P_8S_{11}, to be formed when a mixture of the tetritatrisulphide and a carbon disulphide soln. of not enough sulphur to form P_3S_6 is heated in a sealed tube at 180°. The product is separated mechanically from the P_3S_6. The same sulphide was said to be formed by heating the tetritatrisulphide with P_2S_3 or P_2S_5 in the presence of carbon disulphide at 180°. The crystals are not identical with those of P_4S_5, and both E. Dervin, and R. Boulouch believe that the product is probably a solid soln. R. Boulouch reported the formation of *phosphorus tritapentasulphide*, P_3S_5, in small crystals by the action of sulphur on an excess of phosphorus dissolved in carbon disulphide containing a little iodine. This is probably not a chemical individual, but rather a solid soln. The *phosphorus persulphide* or *dodecasulphide*, P_2S_{12}, of J. J. Berzelius, was obtained by dissolving sulphur in liquid hemisulphide. The product appeared in crystals resembling those of sulphur. This product is probably a solid soln. of sulphur in one of the other phosphorus sulphides, although it appears as a maximum on H. Giran's m.p. curve, Fig. 51. A. Dupré's *phosphorus hexasulphide*, P_2S_6, obtained in an analogous manner, is probably a similar solid soln. with less sulphur. G. Ramme apparently so regarded it.

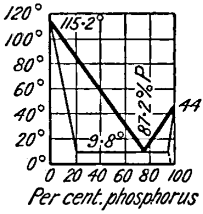

FIG. 51.—Fusion Curve of Mixtures of Phosphorus and Sulphur.

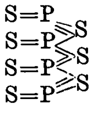
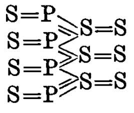
According to R. Boulouch, the f.p. curve of varying proportions of phosphorus and sulphur associated by fusion at temp. below 100° consists of two lines, Fig. 51, which cut sharply at the eutectic temp., 9·8° and 22·8 per cent. of sulphur. Hence, there is no evidence of the formation of a definite compound of the two elements below 100°. Mixed crystals, or solid soln., rich in sulphur are formed, and these are isomorphous with octohedral sulphur ; similarly, mixed crystals, or solid soln., rich in phosphorus, are isomorphous with phosphorus. F. Isambert found that when a mixture of phosphorus, even with a large excess of sulphur, is distilled at 100° in vacuo, all the phosphorus distils over, and a residue of sulphur remains. H. Giran heated mixtures of the two elements in sealed tubes at about 200°, and after cooling, found the temp. at which complete liquefaction occurred. The results are indicated in Fig. 52. The formation of four different compounds is indicated by four temp. maxima on the curves representing the dependence of the liquefaction temperature on the composition. The maximum temp. are 167°, 296°, 272°, and 314°, the corresponding composition being expressed by the formulæ P_4S_3, P_2S_3, P_2S_5, and P_2S_6 respectively. The four eutectics at —40°, +46°, +230°, and +243° correspond approximately with the compositions P_2S, PS, PS_2, and PS_3 respectively. The mixtures of sulphur and phosphorus, which are liquid at the ordinary temp., exhibit super-cooling to a marked degree; solidification can only be brought about by cooling to about —80°. R. Boulouch added that there is not a eutectic at —40° with 33·5 per cent. of sulphur; and he showed that instead of the curve travelling *DCBA*, it travels *DBA* with the eutectic at —7°. The appearance of precision conveyed by Fig. 51 is illusory. The whole subject wants carefully overhauling. A. Stock and H. von Bezold said that the existence of only the following compounds: P_4S_3, P_4S_7, P_3S_6, and P_2S_5 or P_4S_{10} can be regarded as definitely established. Unlike H. Giran, they obtained two maxima between P_2S_5, m.p. 276°, and P_4S_3, m.p. 166°—the one at 303° corresponded with P_4S_7, and the one at 298° with P_3S_6. M. Rudolph, and B. Herscovici also found a maximum at 311°, corresponding with P_4S_8, on the f.p. curve of the binary system P_4S_3–P_2S_5. The —40° observed by H. Giran is probably due to a state of surfusion produced by rapid cooling. R. Boulouch found that the f.p. curve of crystals rich in P_4S_3 consists of two portions at different inclinations, and it is the intersection of the second portion with the curve of solidification of crystals rich in phosphorus which determines the eutectic point. The point of intersection of the two portions of the curve of solidification of crystals rich in P_4S_3 occurs where the conc. of sulphur is 36 per cent. and the temp. 44° (that is, the m.p. of the phosphorus), and ought to be regarded as a transition point. The most probable explanation is that above 44° phosphorus sulphide, P_4S_3, is deposited, and below that temp. a mixture of phosphorus and phosphorus sesquisulphide. A. Gorboff made some observations on the composition of the eutectic. J. Mai represented P_4S_3, P_4S_7, and P_4S_{10} by the following graphic formulæ:

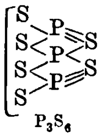
P_4S_3



P_4S_7



P_4S_{10}



P_3S_6

In addition to the numerous compounds reported as a result of the direct union of the elements by fusion, a number have been obtained—by B. Corenwinder, R. Boulouch, A. Seidel, etc.—by crystallization from soln. of phosphorus and sulphur in carbon disulphide. A. Helff said that no compound is formed from soln. of the two elements in carbon disulphide. For A. Delachaux's observations on the production of phosphorus sulphides by the action of hydrogen sulphide or sulphur on phosphine, *vide supra.*

G. Lemoine reported the formation of **phosphorus tetritatrisulphide,** P_4S_2, by heating red phosphorus and sulphur to about 160°; F. Isambert said that yellow phosphorus can be employed if the violence of the reaction be moderated by admixture with sand. Many others have since reported the formation of this compound by the direct union of the elements—*e.g.*, A. Helff, H. von Bezold, G. Ramme, J. Mai and F. Schaffer, E. Scharff, and M. Rudolph. G. Lemoine, H. Rebs, and H. Schulze said that the tetritatrisulphide is also formed by heating the so-called tetritasulphide to about 100°, in an indifferent gas; E. Dervin, by heating the hemitrisulphide or the octitahenasulphide with carbon disulphide in a sealed tube at 200°; and A. Besson, by the action of phosphine on thionyl, sulphuryl, or pyrosulphuryl chloride. H. Giran's curve, Fig. 52, gives an idea of the part played by this compound in the binary system: P–S.

A. Stock and H. von Bezold said that this compound is obtained by heating the calculated amounts of sulphur and red phosphorus in a sealed tube to 180°, and crystallizing the raw materials from alcohol. A. Stock and M. Rudolph recommend the following mode of preparation:

> An excess of red phosphorus is mixed with finely-powdered sulphur, and the mixture heated in a wide tube, sealed at one end, in an atmosphere of carbon dioxide. The temperature is first gradually raised to 100°, and then the reaction started by stronger local heating near the surface of the mixture. When the reaction has spread through the whole mass, the tube is strongly heated until the contents begin to distil, otherwise higher sulphides of phosphorus are formed; the reaction product, which consists of red phosphorus and tetraphosphorus trisulphide, is allowed to cool in the atmosphere of carbon dioxide. The trisulphide may be separated from the red phosphorus by extraction with carbon bisulphide or by distillation in an atm. of carbon dioxide, but in both cases it is somewhat impure.

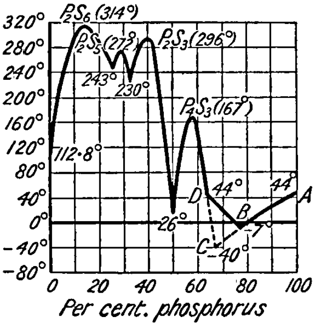


FIG. 52.—Fusion Curve of Mixtures of Phosphorus and Sulphur.

This sulphide occurs in commerce under the name *phosphorus sesquisulphide*, where it is employed in the manufacture of matches. Analyses have been discussed by M. Rudolph, C. T. Mörner, H. Henzerling, J. Mai and F. Schaffer, E. G. Clayton, L. Aronstein, and C. van Eijk. E. G. Clayton found 83·34–97·86 per cent. of P_4S_3; water and volatiles lost at 100°, 0·18–8·74 per cent.; phosphoric acid, 1·23–2·14 per cent.; uncombined sulphur, 0·17–4·17 per cent.; calcium phosphate, up to 3·30 per cent.; calcium sulphate, up to 0·27 per cent.; iron oxide, etc., up to 1·72 per cent.; and silicious matters, up to 0·80 per cent. The objectionable impurity is free phosphorus. J. Mai and F. Schaffer showed that if too high a temp.—say 340°—is employed in its preparation, phosphorus will be present; and if too low a temp. be employed, the substance cannot be conveniently powdered. The crude commercial sulphide, which had been made by gradually heating red phosphorus with some excess of sulphur to a temperature of 330° in a current of carbon dioxide, was heated for 2–3 hours at 180° in a stream of dry carbon dioxide; the evolution of hydrogen phosphide was observed, and the formation of a crystalline sublimate; this was obtained in much larger quantity when the sulphide was heated at 340°. This sublimate was luminescent at 40° when observed in the dark, and at that temperature evolved a white vapour; it melted at 155°–164°, was readily soluble in carbon disulphide, and is undoubtedly phosphorus tetritatrisulphide free from phosphorus. In this state, it melts to an amber-yellow liquid, and not red as is usually stated. A further series of experiments were made with phosphorus sesquisulphide, which had been obtained from the crude product by repeated crystallization from a mixture of carbon disulphide and petroleum. When heated at 40°–50°, it luminesces strongly, emits a white vapour, and becomes slowly oxidized. When boiled with water luminescence continued as long as the water was boiled, but ceased as soon as the boiling was stopped. After prolonged distillation with steam, a minute quantity of solid distillate was obtained which consisted mainly of phosphorus tetritatrisulphide mixed with a small quantity of oxidized substances; the condensed steam contained hydrogen sulphide.

Analyses of the purified compound by G. Lemoine, G. Ramme, H. Schulze, J. Mai and F. Schaffer, L. Wolter, and A. Stock and co-workers are in agreement with the formula P_4S_3. G. Lemoine found that the fractional crystallization and fractional sublimation of the tetritatrisulphide gave no evidence of a heterogeneity. The vap. density determinations of G. Ramme, G. Lemoine, F. Isambert, A. Helff, and A. Stock and H. von Bezold are in agreement with this formula, so also is the mol. wt. calculated from the effect of this sulphide on the b.p. of carbon disulphide by A. Helff, and A. Stock and H. von Bezold. The fused product appears as a yellow crystalline mass, and, according to G. Lemoine, when crystallized from its soln. in carbon disulphide, phosphorus trichloride, or thiophosphoryl chloride, appears in pale yellow, rhombic prisms. G. Lemoine gave 2·1 for the sp. gr.; F. Isambert, 2·00 at 11°; and A. Stock and H. von Bezold, 2·03 at 17°. G. Lemoine found the m.p. to be 142°, but when the sulphide was crystallized from its soln. in carbon disulphide, G. Ramme obtained a much higher value, namely, 166°; F. Isambert gave 167°; H. Rebs, 165°; A. Helff, 165°–166°; J. Mai and F. Schaffer, 155°–164°; and E. Scharff, 167°. H. Giran gave 167°, and added that the presence of an excess of either sulphur or phosphorus depresses the m.p.—Fig. 52. A. Stock and co-workers obtained 171°–172·5° for the m.p. F. Isambert gave 380° for the b.p.; J. Mai and F. Schaffer, 408°–418°; G. Lemoine, 410°–420°; and A. Stock and M. Rudolph, 407°–408° at 760 mm. As indicated above, vap. density determinations by G. Ramme, G. Lemoine, and A. Helff ranging from 7·43 to 8·17 are in agreement with 7·62 (air unity) calculated for the tetritatrisulphide; A. Stock and H. von Bezold obtained:

	700°	750°	800°	850°	900°	950°	1000°
Vap. density .	219	213	202	185	182	179	179

in agreement with the calculated value 220° when the temp. is near 700°; at higher temp., dissociation becomes appreciable. A. Helff, and A. Stock and M. Rudolph found the mol. wt. calculated from the raising of the b.p. of benzene to be 228 to 264 when the theoretical value is 220°. The heat of formation of the tetritatrisulphide is, according to F. Isambert, (4P,3S)=16·4 Cals. He added that since the transformation of ordinary into red phosphorus is accompanied by the production of a greater amount of heat, namely, 20 Cals., the red phosphorus and sulphur ought not to combine directly. The fact that they do combine at an elevated temp., 180°, shows that the vap. press. of red phosphorus at this temp. must be high enough to convert some red phosphorus into ordinary phosphorus at the moment of combination. Even at 260° red phosphorus unites with sulphur only slowly and without an explosion, and then only an insignificant thermal change accompanies the formation of the tetritatrisulphide. A. Stock and F. Gomolka also found the reaction between sulphur and red phosphorus to be slow at 200°.

According to G. Lemoine, air at ordinary temp. has no action on the tetritatrisulphide. This sulphide inflames in air at about 100°, and it can be distilled between 300° and 400°; it can, however, be volatilized completely at 260° in a current of carbon dioxide. A. Stock and M. Rudolph observed a slight decomposition when the molten sulphide is kept for a month in a sealed glass tube, but they added that this may be an effect of the presence of traces of moisture. When distilled, A. Stock and H. von Bezold observed that the distillate was slightly richer in phosphorus—having 44·0 instead of 43·7 per cent. of sulphur; and the residue in the retort slightly richer in sulphur—having 55·8 instead of 56·3 per cent. of phosphorus. R. Böttger, and W. Wicke observed that phosphorus sulphide is decomposed by light.

According to E. Scharff, when the tetritatrisulphide is heated in **air** at 80°, in darkness, a greenish flame hovers over the mass, and a white cloud with a characteristic odour appears; if oxygen be introduced into the vessel, the luminescence is at first intensified, and it then disappears. As with phosphorous oxide, there is a maximum press. favourable for the luminescence. No ozone was detected. Since the tetritatrisulphide at an elevated temp. is partially resolved into ordinary phosphorus, it might be thought that the luminescence is produced by the oxidation of phosphorus or of phosphorous oxide; but J. Mai and F. Schaffer (*vide supra*), and E. G. Clayton agree that the glow is different from that of yellow phosphorus. E. Scharff observed that in **oxygen** at 70° and 368·48 mm. press., there appears abruptly, just over the sulphide, a clear, intermittent luminescent glow which approaches the steady state as the press. diminishes, until at 294·59 mm.

press. the luminescence is continuous; as the press. is increased, the luminescence again becomes intermittent, and vanishes at 387·67 mm. press. The results at different temp. are indicated in Table VIII, for dry and moist oxygen. Normally, the luminosity begins at 65°, and it burns at 90° with a greenish flame, forming phosphoric and sulphurous oxides. The press. at which the luminescence ceases is generally higher than that at which it starts, and the difference is greater, the higher the temp.; and if the press. is again reduced, the luminescence starts at a higher press. than it originally did. The luminescence is not much affected if toluene vapour be also present; and it is feeble in the presence of turpentine, and the intermittent phenomenon persists. Iodobenzene, benzene, chloroform, carbon disulphide, and alcohol give an enfeebled luminescence; and with amylene the sulphide suddenly ignites at 90° without showing the luminescence.

TABLE VIII.—EFFECT OF TEMPERATURE AND PRESSURE ON THE LUMINESCENCE OF PHOSPHORUS TETRITATRISULPHIDE.

Dry oxygen.				Moist oxygen.		
Temp.	Begins.	Steady.	Ends.	Begins.	Steady.	Ends.

The tetritatrisulphide was found by G. Lemoine to be but slightly decomposed by cold **water**, while boiling water slowly forms hydrogen sulphide and phosphoric acid—for J. Mai and F. Schaffer's observations with the commercial sulphide, *vide supra*. A. Stock and M. Rudolf said that this sulphide is more stable towards water than any of the other phosphorus sulphides, for it is only gradually decomposed even by boiling water. G. Lemoine said that the sulphide is slowly but completely decomposed by **chlorine** water, forming, according to F. Isambert, phosphoric and sulphuric acids. F. Isambert found that a soln. of **iodine** in carbon disulphide rapidly attacks the tetritatrisulphide yielding phosphorus triiodide, but has no action on compact red phosphorus, a difference due to the fact that the formation of phosphorus triiodide develops less heat than the conversion of ordinary phosphorus into red phosphorus. The phosphorus does not exist in the tetritatrisulphide as red phosphorus, all the latter having been converted into the ordinary variety at the moment of combination. A. Wolter said that by cooling a mixed carbon disulphide soln. of iodine and the tetritatrisulphide, yellow crystals of the iodide $P_4S_3I_2$ are formed. G. Lemoine found that **hydrochloric acid** has scarcely any action in the cold. According to E. Dervin, when two parts of **sulphur** and one of phosphorus tetritatrisulphide are dissolved in carbon disulphide in a sealed tube, and the soln. exposed to the light for one or two months, fine pale-yellow transparent needles of the sulphide, P_3S_6, are formed. This compound is not affected by heating under pressure with carbon disulphide. In the above reaction crystalline spherical grains of P_8S_{11} are also formed. R. Boulouch said that if a crystal of iodine be added to a carbon disulphide soln. of sulphur and phosphorus tetritatrisulphide, phosphorus tetritapentasulphide gradually separates out. G. Lemoine found that **sulphuric acid** has scarcely any action in the cold. According to A. Stock, liquid **ammonia** in a sealed tube forms a reddish-brown soln. which becomes dark red, and finally forms a brown jelly; when the tube is opened phosphine escapes with the excess of ammonia, and there remains a viscid mass containing a thiophosphate and other substances. G. Lemoine said that cold **nitric acid** dissolves the sulphide with the separation of sulphur; **aqua regia** dissolves the sulphide completely. F. Isambert made analogous observations. He also observed that if some tetritatrisulphide be placed on a stick of phosphorus, the latter melts at the point of contact; and if a mixture of **phosphorus** and its tritatrisulphide be heated at 100° in vacuo, phosphorus distils over carrying with it a small portion of the tetritatrisulphide. E. Dervin found that when the tetritatrisulphide is mixed with **phosphorus tetritahexasulphide,** or **phosphorus tetritadecasulphide,** in carbon disulphide soln., and heated to 180° in a sealed tube, the tritahexasulphide and octitahenasulphide are formed. A. Stock and co-workers examined the f.p. curves of mixtures of phosphorus tetritatrisulphide with **phosphorus tetritadecasulphide,** and found two eutectics with a maximum corresponding with phosphorus tetritoctosulphide; while with **phosphorus tetritaheptasulphide** there is only one eutectic. G. Lemoine found that the tetritatrisulphide dissolves in **alcohol,** and **ether** with decomposition. The solubility in **carbon disulphide** was observed by G. Lemoine, and H. Schulze; the former said that 100 parts of the solvent dissolve 60 parts of the tetritatrisulphide, and A. Stock and M. Rudolph gave for the solubility in 100 parts of carbon disulphide at —20°, 0°, and 17°, respectively 11·1, 27·0, and 100 parts of the tetritatrisulphide, while 100 parts of **benzene** at 17° and 80° dissolve respectively 25 and 11·1 parts; and 100 parts of **toluene** at 17° and 111°, dissolve respectively 31·2 and 15·4 parts. The yellow soln. in carbon disulphide gives a broad absorption band from the middle of the blue to the violet. G. Lemoine said that a cold soln. of **potassium hydroxide** acts on the tetritatrisulphide with the development of much heat-forming phosphine, hydrogen, potassium sulphide, and potassium hydrophosphite—*vide infra,* oxythiophosphates. A. Stock and M. Rudolph found that finely-divided phosphorus tetritatrisulphide reacts vigorously with a soln. of potassium hydroxide when hydrogen and phosphine (1 : 1 or 2 : 1) are evolved. At ordinary temp., the evolution of gas lasts for days. If the reddish-brown soln. be acidified immediately after it is prepared, a yellow precipitate resembling hydrogen diphosphide is formed. This precipitate is not formed with soln. that have been kept for some time. According to M. Frouin, when this sulphide is in contact with the moisture of the skin, it evolves hydrogen sulphide; and, probably by reason of the formation of volatile phosphorus compounds, the vapours are said to be more poisonous than those of ordinary phosphorus.

F. A. Kekulé, G. Lemoine, A. Michaelis, and F. Isambert reported *phosphorus trisulphide,* P_2S_3, or **phosphorus tetritahexasulphide,** P_4S_6, to be formed by melting eq. proportions of red phosphorus and sulphur in an atm. of carbon dioxide. J. Mai could not obtain a homogeneous product in this way; and A. Helff said that the product is never homogeneous since the tetritatri- and tetritahepta-sulphides can be separated from the product. According to L. Springer, the loss due to the burning of the mixture of red phosphorus and sulphur in the preparation of phosphorus trisulphide is avoided by at first heating only a small portion of the mixture in a fireclay crucible until combination takes place, removing the burner and then adding the rest of the mixture in small portions at a [time. If the first charge takes fire, it is extinguished by means of sand, and after each subsequent addition the lid is replaced on the crucible. The action takes place quietly, causing only a slight puff and formation of fume. J. J. Berzelius obtained it as a sublimate by heating either the hemisulphide or manganese diphosphodisulphide, MnS.P_2S, and sulphur; H. Schulze, by heating the so-called tetritasulphide and sulphur; G. S. Sérullas, by the action of hydrogen sulphide on phosphorus trichloride—J. H. Gladstone used phosphorus tribromide, and L. Ouvrard, the triiodide; A. Besson, by the action of hydrogen iodide on warm thiophosphoryl chloride; and L. Ouvrard, by heating phosphorus disulphodiiodide in vacuo at 300°, or by treating the same compound with water; and by the decomposition of the sulphotetriodide. F. Krafft and B. Neumann purified it by sublimation in vacuo. The tetritahexasulphide is variously described as a white or yellowish-white crystalline mass. Analyses by H. Schulze, J. J. Berzelius, and L. Ouvrard agree with the empirical formula P_2S_3, and F. Isambert found the vap. density 10·2–12·0 in agreement with 10·9 required for P_4S_6. G. Ramme could not obtain this compound by heating the elements in the presence of carbon disulphide. J. Mai, A. Helff, E. Dervin, R. Boulouch, and A. Stock and co-workers all doubted the existence of this product as a chemical individual. It appears as a maximum on H. Giran's fusion curve, Fig. 51; but A. Stock and co-workers did not verify this.

The following properties have been ascribed to the tetritahexasulphide: H. Schulze said that when heated it becomes orange-yellow, melts, and then sublimes. G. Lemoine said that it fuses at 290°, and F. Giran, 296°. J. J. Berzelius said that it sublimes below the b.p. of sulphur. F. Isambert gave 490° for the b.p., and M. von Recklinghausen, 545°–546·5°. According to J. J. Berzelius, this sulphide does not fume or luminesco in darkness; and J. J. Berzelius, and G. Lemoine found that it is readily decomposed in moist *air*, forming sulphur and phosphoric acid. It burns with a yellowish-white flame when heated in air. F. A. Kekulé, and G. Lemoine found that with *water* it forms hydrogen sulphide and phosphoric acid. A. Michaelis said that with *bromine* it forms a trisulphotetrabromide; and L. Ouvrard, with *iodine* in the presence of carbon disulphide, disulphodiiodide. A. J. Balard found that with *hypochlorous acid* it forms chlorine, and sulphuric, phosphoric, and hydrochloric acids. According to A. Bineau, it absorbs *ammonia* very slowly, and in about 6 months a yellow solid with an hepatic odour is formed. J. J. Berzelius said that the sulphide is soluble in aq. ammonia—*vide infra*, the action of alkali-lye. L. Ouvrard found that it reacts with *phosphorus diiodide:* $P_2S_3+P_2I_4=P_4S_3I_2+2I$, and with *phosphorus triiodide:* $2P_2S_3+2PI_3=3P_2S_2I_2$, or with an excess of the iodide: $P_2S_3+4PI_3=3P_2SI_4$. E. Dervin said that when heated with *phosphorus tetritatrisulphide* in the presence of carbon disulphide at 180°, it forms the so-called pentasulphide, and octitahenasulphide. F. Krafft and B. Neumann observed that with *arscnic* at 240°–300°, arsenic trisulphide and phosphorus are formed; and an analogous reaction occurs with *antimony* at 325°. When heated with *carbon disulphide* under press., it forms the tetritatrisulphide and tritahexasulphide. F. A. Kekulé said that with *acetic acid*, thioacetic acid is formed; and L. H. Friedburg, with *succinic acid*, thiophene is produced. N. Speransky studied its action on *menthone*. J. J. Berzelius found that the tetritahexasulphide is soluble in cold aq. soln. of the *alkali carbonates* with the separation of sulphur; it is also readily soluble in soln. of the *alkali hydroxides*. The pale yellow soln. give with acids a white flocculent precipitate of the original sulphide. G. Lemoine said that the evaporation of the soln. with very dil. alkali-lye yields alkali phosphite: but if the alkali-lyo be in excess, oxythiophosphites are formed. J. J. Berzelius, and L. Ferrand found that it unites with *metal sulphides*, forming thiophosphates.

According to J. Mai, some **phosphorus tetritaheptoxide,** P_4S_7, is formed during the distillation of phosphorus tetritahexasulphide in vacuo under 11 mm. press., at 290°–300°. The product was heated with carbon disulphide in an atm. of carbon dioxide in a sealed tube at 150°–160°. The crystals so formed are pressed between filter-paper, and freed from the solvent by warming them in vacuo. A. Stock and H. von Bezold made it by melting together 2 gram-atoms of red phosphorus and three of sulphur, and extracting the mass with carbon disulphide with a reflux condenser; by heating a soln. of the tetritatrisulphide and the tetritadecasulphide in carbon disulphide at 100°; and A. Stock and B. Herscovici, by heating an intimate mixture of red phosphorus and sulphur in proportions eq. to P_4S_7 with 5 per cent. P_4S_3 is heated in a hard glass tube until distillation begins. The cooled product is then recrystallized from carbon disulphide in which the heptasulphide is sparingly soluble and the trisulphide readily soluble. The pale yellow or colourless, prismatic crystals decompose rapidly in air with the evolution of hydrogen sulphide. This compound, said A. Stock and B. Herscovici, is more sensitive to moisture than is the case with the tetritatrisulphide. The analyses of J. Mai, A. Helff, and A. Stock and co-workers and the vap. press. 11·63–11·71 (air unity) of A. Helff are in agreement with the formula P_4S_7. A. Stock and B. Herscovici found the vap. density up to 700° in agreement with 348 calculated for P_4S_7; but at higher temp. decomposition occurs, and the mol. wt. falls to less than half this value:

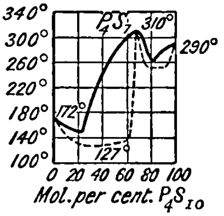

FIG. 53.—Melting-point Curve of Mixtures of P_4S_6 and P_4S_{10}.

	700°	750°	800°	850°	900°	950°	1000°
Mol. wt. . .	337	323	202	193	179	173	167

The sp. ht. is 2·19 at 17°. The sulphide sinters at 305°–308°, and the m.p. is 310°, and it is not changed by repeated extraction with carbon disulphide. It boils at 523° and 760 mm. The m.p. curve of binary mixtures of phosphorus tetritahexa- and tetritadecasulphide is indicated in Fig. 53. The m.p. curve, said A. Stock, has a single maximum at 310° corresponding with P_4S_7, and eutectics at 127° and

47·5 per cent. of sulphur, and 248° and 69 per cent. of sulphur. Although only sparingly soluble in carbon disulphide, this is the best solvent known for this sulphide—100 parts of carbon disulphide dissolve 0·0050 part of the tetritaheptasulphide at 0°, and 0·0286 part at 17°.

A. Seidel prepared *phosphorus disulphide*, or **phosphorus tritahexasulphide,** P_3S_6, by heating the calculated quantities of ordinary phosphorus and sulphur with carbon disulphide in a sealed tube at 210°, and G. Ramme observed its formation when the at. proportions of the phosphorus and sulphur range from 2 : 3 to 1 : 6. The raw product was purified by crystallizing it six times from carbon disulphide in a sealed tube. E. Dervin obtained it by exposing to direct sunlight a soln. of 2 parts of sulphur and one of phosphorus tetritatrisulphide in carbon disulphide; the crystalline precipitate formed needle-like crystals in two months' time. He obtained it by heating the so-called octitahenasulphide with carbon disulphide at 200° in a sealed tube; by heating the tetritatrisulphide and tetritahexasulphide with carbon disulphide at 180°—some octitahenasulphide was formed at the same time; and by heating the tetritahexasulphide with carbon disulphide in a sealed tube—some tetritatrisulphide was formed at the same time. R. Boulouch obtained this sulphide by exposing to sunlight for a couple of days a carbon disulphide soln. of phosphorus with an excess of sulphur in the presence of a crystal of iodine. J. Mai obtained the tritahexasulphide by distilling a molten mixture of sulphur and phosphorus in the proportion 2 : 1; and A. Helff by melting together eq. proportions of the constituent elements. J. Mai added that when an intimate mixture of phosphorus and sulphur in the at. proportion 1 : 2, is heated in an atm. of carbon dioxide, and the product distilled, a yellow crystalline substance, P_4S_3, passes over. The later fractions consist of a mixture of phosphorus tritahexasulphide and tetritadecasulphide which cannot be separated by fractional distillation owing to the close proximity of their b.p. A. Stock obtained no evidence of the existence of this sulphide on the m.p. curve of mixtures of phosphorus tetritatri- and tetritadeca-sulphides, Fig. 53; and H. Giran's result, Fig. 52, is explained by the imperfect equilibrium attained at 200°—he should have employed 300°. H. von Bezold, however, maintained that there is evidence of the formation of this sulphide on the m.p. curve of mixtures of the tetritatri- and tetritadecasulphides, but the compound readily dissociates into the tetritaheptasulphide, etc., on cooling.

The analyses of G. Ramme, J. Mai, E. Dervin, A. Helff, and A. Seidel agree with the empirical formula PS_2; and the vap. density determinations of G. Ramme, and A. Helff agree with the formula P_3S_6, while those of J. Mai agree with P_4S_8. H. von Bezold obtained a result similar to that of J. Mai from mixtures of phosphorus tetritadecasulphide and tetritatri- or tetritaheptasulphide. H. von Bezold's result for the effect of the tritahexasulphide on the b.p. of carbon disulphide agrees with P_3S_6. A. Seidel, G. Ramme, A. Helff, R. Boulouch, and E. Dervin agree that the compound forms pale yellow,. transparent, needle-like crystals. J. Mai said that this sulphide easily decomposes, and after it has been in a desiccator for a short time, there is a separation of sulphur. A. Seidel gave 248°–249° for the m.p.; G. Ramme, and A. Helff, 296°–298°; E. Dervin, 296°; and H. von Bezold, 298°. J. Mai found that at 10–11 mm. press., this sulphide gives a pale green vapour between 335°–340°, and the distillate has the composition P_3S_9. M. von Recklinghausen gave 516°–519° for the b.p. J. Mai said that phosphorus tritahexasulphide readily decomposes; and G. Ramme, that when heated with water for 5–6 hrs. in a sealed tube, hydrogen sulphide and phosphorous and phosphoric acids are formed, while a residue remains which is not soluble in carbon disulphide, and which does not melt at 310°. When heated with phosphorus, the tetritatrisulphide is formed. This sulphide was found by A. Stock to dissolve in liquid ammonia, forming a brown soln. which after some time deposits crystals of ammonium amidothiophosphate; and when the ammonia is evaporated, some phosphine escapes, and there remains a complex substance.

F. A. Kekulé obtained **phosphorus pentasulphide,** P_2S_5—that is, **phosphorus tetritadecasulphide,** P_4S_{10}—by melting phosphorus and sulphur in the correct proportions. A. Stock and K. Thiel said that the product so obtained is always contaminated with some lower sulphides, so that the commercial product is really a mixture. V. and C. Meyer, H. Goldschmidt, and A. Helff obtained this sulphide from its elements. H. Rebs melted a mixture of red phosphorus and sulphur in the correct proportions; digested the product with carbon disulphide in a sealed tube; and, on cooling the soln., obtained crystals of this compound. A. Stock and B. Herscovici heated a mixture of red phosphorus and sulphur in theoretical proportions, but with one per cent. excess sulphur in an atm. of carbon dioxide. The temp. is gradually raised, and near 100°, after the reaction has spread through the whole mass, the temp., the contents begin to distil. The finely powdered product is heated in an evacuated sealed tube for several hours at 700°, and the resulting mass recrystallized several times from carbon disulphide. The crystals are finally dried at 100° in a current of hydrogen. A. Stock and W. Scharfenberg also prepared this sulphide from its elements. G. Ramme heated a carbon disulphide soln. of phosphorus and sulphur in a sealed tube for 8–10 hrs. at 210°, and recrystallized the product from its soln. in carbon disulphide in a sealed tube. E. Dervin, A. Stock, A. Stock and H. von Schönthan, and A. Stock and K. Thiel used modifications of this mode of preparation. F. Isambert obtained this sulphide by the action of sunlight on a soln. of sulphur and phosphorus in carbon disulphide. J. J. Berzelius obtained it by melting a mixture of phosphorus hemisulphide or manganese phosphodisulphide, and sulphur; or by heating molten phosphorus hemisulphide in a current of hydrogen chloride, and distilled the resulting product; A. Pauli, by the action of dry hydrogen sulphide on phospham at a red-heat; A. Besson, by the action of hydrogen sulphide on phosphoryl chloride, or of hydrogen iodide on warm thiophosphoryl sulphide; and also by heating phosphorus dioxytrisulphide in vacuo at 150°; A. Stock, by the spontaneous decomposition of dithiopyrophosphoric acid: $4H_4P_2O_2S_5 = 3P_2S_5 + 2H_3PO_4 + 5H_2S$. E. Baudrimont, by passing the vapour of thiophosphoryl chloride through a red-hot tube; A. Stock, by leaving a soln. of phosphoryl bromide in liquid hydrogen sulphide for a long time in contact with phosphorus pentoxide; and evaporating the liquid. There remains phosphorus tetritadecaphosphide. According to A. Stock, when ammonium trithiophosphate is treated with liquid hydrogen sulphide, and washed with carbon disulphide, it furnishes phosphorus tetritadecasulphide.

Analyses were made by V. and C. Meyer, A. Besson, H. Goldschmidt, A. Stock and co-workers. The results agree with the formula P_2S_5. The vap. density by V. and C. Meyer, A. Helff, and F. Isambert agrees closely with 7·67 required for P_2S_5, but W. A. Tilden and R. E. Barnett add that the low value is due to the dissociation of the molecule. A. Stock and H. von Bezold found the mol. wt. by the vap. density method decreases rapidly with rise of temp., being 208 at 600°; 196 at 650°, 185 at 700°; 144 at 800°; 136 at 900°; and 133 at 1000°. A. Stock and W. Scharfenberg made analogous observations. The mol. wt. calculated from the rise in the b.p. of carbon disulphide by the dissolved sulphide is in agreement with the formula P_4S_{10}. A. Stock and W. Scharfenberg said that the commercial sulphide is not a chemical individual and has a m.p. 255°; when recrystallized from carbon disulphide it has 3 per cent. less sulphur than is needed for P_4S_{10}. According to A. Stock and K. Thiel, the pale yellow crystalline tetritadecasulphide exists in two forms. One—the ordinary—form is sparingly soluble in carbon disulphide, and the other form is readily soluble. At 240°, the ordinary form is orange, the other yellow; the ordinary form shows no signs of melting at 273°, but begins to melt at 275°–276°, and forms a clear liquid at 279°; the other form sinters a little at 247°, is nearly all melted, and forms a clear liquid at 276°. The ordinary form is obtained by repeated crystallization from hot carbon disulphide; the other form is obtained by the rapid condensation of the vapour of the ordinary sulphide, extracting the mass with cold carbon disulphide and crystallization from the resulting soln. The ordinary sulphide gives pale yellow crystals which are fairly stable in air, the other form is nearly white, and gives off hydrogen sulphide in air. The two forms cannot be separated by fractional crystallization from carbon disulphide. The form which is more readily soluble in carbon disulphide does not exhibit a sharp m.p. While ebullioscopic determinations of the mol. wt. of the ordinary form in carbon disulphide show it to have the formula P_4S_{10}, similar determinations with the form which is more readily soluble in carbon disulphide, do not agree with the formula P_4S_{10}; the mol. wt. being smaller than that in accordance with this formula, the product is probably a mixture. The sp. gr. of the ordinary form is 2·03, that of the other form is 2·08. V. and C. Meyer, and A. Helff gave 274°–276° for the m.p.; A. Stock, 275°–276°—*vide supra.* A. Stock and B. Herscovici found the m.p. of the sulphide crystallized 10 times from carbon disulphide is 284°–291°, and there is no appreciable difference in the m.p. of the sulphide kept in vacuo for 3 months. A. Stock said that there is a partial decomposition on melting. J. J. Berzelius said that this sulphide boils at a higher temp. than sulphur, and that the vapour is paler in colour than that of sulphur. J. Mai found that the sulphide distils at 332°–340° under 10–11 mm. press., forming a pale greenish-yellow vapour. W. Hittorf gave 530° for the b.p.; H. Goldschmidt, 518° at 728·5–734 mm.; F. Isambert, 520°; M. von Recklinghausen, 523·6°; and A. Stock and B. Herscovici, 513°–515° at 760 mm. with partial decomposition; the decomposition, added A. Stock and B. Herscovici, occurs under all circumstances at 530° in a current of carbon dioxide, or in vacuo. C. Graebe, and W. Knecht recommended the use of this sulphide for the vapour-bath in vap. density determinations. R. Robl observed no fluorescence when the pentasulphide is exposed to ultra-violet light.

J. J. Berzelius found that phosphorus tetritadecasulphide burns when heated in **air** giving the characteristic phosphorus flame; while in moist air, it decomposes as readily as the tetritahexasulphide, forming phosphoric acid. F. A. Kekulé represented the decomposition by **water**: $P_2S_5+8H_2O=2H_3PO_4+5H_2S$; and A. Stock and B. Herscovici added that water attacks this sulphide slowly at ordinary temp., and rapidly when heated. L. Carius found that when a mixture of this sulphide and **thionyl chloride** is heated at 150° in a sealed tube it forms sulphur monochloride and phosphorus pentoxide, and H. Prinz represented the reaction: $6SOCl_2+2P_2S_5=4PSCl_3+3SO_2+9S$. R. F. Hunter was unable to brominate phosphorus pentasulphide by treating the soln. in chloroform or carbon disulphide with **bromine**; and a similar result was obtained with **iodine.** J. J. Berzelius said that this sulphide dissolves in aq. **ammonia** in the same manner as a deliquescent salt dissolves in water. A. Stock and B. Hoffmann found that ammonia unites additively with the sulphide, forming phosphorus dodecamminotetritadecasulphide, $P_4S_{10}.12NH_3$; and A. Stock obtained the same product by adding the sulphide to liquid ammonia. This compound is represented as *ammonium diimidopentathiopyrophosphate,* $S\{P(SNH_4)_2(NH)\}_2$; and the corresponding *diimidopentathiopyrophosphoric acid,* $P_2S_5N_2H_6$, or $P_4S_{10}.4NH_3$, *phosphorus tetramminotetritadecasulphide,* has been obtained in an impure form—*vide* phosphorus nitride. E. Glatzel obtained thiophosphoric nitrile, NPS, by the action of **ammonium chloride** on phosphorus tetritadecasulphide. E. Dervin obtained phosphorus tritahexa- and octitahena-sulphides by the fusing of a mixture of this sulphide with **phosphorus tetritatrisulphide** in the presence of carbon disulphide at 180°; R. Weber represented the reaction with **phosphorus pentachloride**: $P_2S_5+3PCl_5=5PSCl_3$; L. Carius, with **phosphoryl chloride**: $P_2S_5+5POCl_3=P_2O_5+5PSCl_3$; and E. Glatzel, with **antimony trichloride**: $P_2S_5+SbCl_3=SbPS_4+PSCl_3$. F. A. Kekulé, and L. Carius observed that the products of the reaction with **alcohol** are mercaptan, ethyl thiophosphates, and hydrogen sulphide; F. A. Kekulé, that **acetic acid** is converted into thioacetic acid; and F. D. Dodge, **acetoxime** into ammonium thiophosphate. T. E. Thorpe observed no reaction with **carbon tetrachloride** at a high temp. H. Rebs found that the tetritadecasulphide dissolves in **carbon disulphide.** A. Stock and B. Herscovici found that at room temp., say 15°, 100 parts of the solvent dissolve 0·222 part of sulphide; at 0°, 0·182 part; and at −20°, 0·0833 part; and A. Stock and K. Thiel found that 100 parts of carbon disulphide dissolve 0·513 part of the ordinary sulphide under conditions where 2·86 parts of the other variety are dissolved. C. Böttinger studied the action of the tetritadecasulphide on **organic acids**; A. Knop, on **aniline**; F. Schwarze, on **phenol**; R. Ciusa, on **benzophenonoxime**; and A. Andreocci, on **antipyrine.**

C. Friedel found that when phosphorus tetritadecasulphide is heated with **metals** on a sealed tube at a red-heat, thiohypophosphates are formed—*vide infra.* According to J. J. Berzelius, the tetritadecasulphide dissolves in a soln. of **alkali hydroxide** much as a deliquescent salt dissolves in water. The soln. has a pale yellow colour, and acids precipitate sulphur with the evolution of hydrogen sulphide. The alkali thiophosphate cannot exist in contact with water. A. Stock and B. Herscovici said that the speed of dissolution in cold soda-lye is slow, and rapid in the hot lye. C. Kubierschky observed that some mono-, di-, and tri-thiophosphates are formed—*vide infra.* J. J. Berzelius found that a cold soln. of an **alkali carbonate** slowly dissolves the tetritadecasulphide with the separation of sulphur, at about 60°. The process of dissolution is violent, no sulphur separates, but carbon dioxide is evolved. When the soln. is boiled, both carbon dioxide and hydrogen sulphide are evolved. J. J. Berzelius, and E. Glatzel observed the formation of complex sulphides by the action of the tetritadecasulphide on **metal sulphides.** L. Ferrand obtained thiohypophosphates and thiophosphate by the action of the tetritadecasulphide at 400° on metal sulphides. E. Glatzel found that **sodium monosulphide** reacts, forming the thiophosphate—*vide infra.* T. E. Thorpe and J. W. Rodger showed that **lead fluoride** or **bismuth fluoride** furnishes thiophosphoryl fluoride; E. Glatzel, that **metal chlorides** form normal thiophosphates; and that **ferric chloride** reacts: $6FeCl_3+P_4S_{10}=3FeCl_2+3FeS_2+4PSCl_3$.

§ 38. Matches

The oldest method of procuring a flame, and one still practised by remote primitive tribes, is by dexterously rubbing together two pieces of dry wood until—in a few minutes—a few glowing particles are produced; these are quickly fanned so as to inflame dry leaves or dried decaying vegetable matters. At a later period, a stream of sparks obtained by striking a piece of steel was directed into dry *tinder*—charred linen—or dried vegetable matter. The sparks soon started the tinder glowing, and this, in contact with some inflammable substance, was fanned into a flame. In the first century of our era, Pliny, in his *Historia naturalis* (**35.** 50), said that dry wood and candles are kindled with sulphurized lamp-wicks. "Fire is struck with flint and steel; and the sulphur seizes the flame, almost sooner than it can be named. The sulphurized lamp-wicks consist either of hempen or tow cords, or small pieces of wood covered with sulphur." Several Latin writers, contemporaneous with Pliny, referred to these sulphurized lamp-wicks—*e.g.* Martial, *Epigrammata* (**1.** 42; **10.** 3), and Juvenal, *Satiræ* (**5.** 46–47)—where the Latin *sulfurata* is sometimes wrongly translated "matches" or "brimstone matches." G. Agricola [1] quoted Pliny's remarks on this subject. In 1604, M. Sandivogius wrote:

> The alchymist also being awakened out of his dream found nothing in his hand but matches which he made of brimstone so that the miserable alchymist learned nothing else by that vision but how to make matches.

The tinder box, with its accompanying flint and steel, was much used up to about 1830, and it was recently revived in the form of lighters made from auer-metal—**5.** 38, 10. Among the early devices for quickly procuring fire were the *pyrophorus powder*, free from phosphorus, which when sprinkled in air became red-hot—*e.g.* the powder obtained by roasting alum with flour, honey, or sugar out of contact with air and hermetically sealed in a glass tube; and the powder obtained by igniting Prussian blue was treated in a similar way. The *pneumatic tinder box*, and *light syringe* of R. Lorenz,[2] contained tinder which was ignited by the heat generated when air was suddenly compressed by a piston. In the *hydropneumatic lamps* or *electropneumatic fire-producers* of H. J. Mayer, and A. Fyfe, hydrogen was kindled by an electric spark; and the various modifications—by W. Eisenlohr, C. H. L. von Babo, S. von Römer, R. Hare, C. H. Pfaff, C. F. Mohr, W. Herapath,

J. Palkl, I. G. R. Schiele, and R. Böttger—of J. W. Döbereiner's *platinum lamp*, in which hydrogen gas is ignited by causing it to impinge on spongy platinum or iridium.

Many attempts were made about the end of the eighteenth century to produce fire conveniently by means of phosphorus. Thus, a particle of phosphorus was rubbed between folds of brown paper, and the resulting flame was used to ignite a splinter of wood tipped with sulphur. This was found to be inconvenient and dangerous. The so-called *phosphoric tapers*, used about 1781, consisted of wax-tapers with their wicks coated with phosphorus. They were enclosed in sealed glass tubes. To obtain a flame, the glass tube was first warmed, then broken, and the phosphorus on the taper, on exposure to air, rapidly oxidized and ignited the taper. The so-called *phosphorus bottles* or *phosphorus boxes—pocket luminaries*, and *portable fire boxes*—used 1786-1810, were internally coated with partially oxidized phosphorus. A splint of wood tipped with sulphur was introduced with the vessel so as to make a little phosphorus adhere. The oxidation of the phosphorus, assisted maybe by friction on a cork, caused the sulphur to ignite. About 1805, *oxymuriate matches*, or *chemical matches*, were made by tipping strips of wood with a mixture of potassium chlorate, sugar, and gum; they were ignited by bringing them in contact with sulphuric acid or asbestos soaked in this acid contained in a bottle. The matches were packed in boxes and sold as *Funkfeuerzeugen*, *briquets phosphoriques*, *inflammable match boxes*; *instantaneous light boxes*, *phosphorus boxes*, *eupyrion*, etc. S. Jones patented a variety which he called *promethians*. These consisted of paper tubes containing a small glass tube holding sulphuric acid coloured by indigo. The glass tube was embedded in a mixture of lycopodium, potassium chlorate, and sulphur. They were ignited by squeezing with pliers the end containing the glass tube so as to set free the acid.

About 1827, J. Walker,[3] of Stockton-on-Tees, invented the first practically useful friction matches. At first, he sold a mixture of potassium chlorate and antimony sulphide made up with gum. He called it *percussion powder*. Afterwards he dipped the tips of strips of cardboard, and then splints of wood, with the mixture, and sold these matches as *friction-lights*. They were ignited by drawing their tips between folded sandpaper held between the finger and thumb. Imitations were sold under the name *lucifers*. Some were tipped with sulphur as well as the chlorate mixture and sold as *chlorate matches*, *lucifer matches*, *allumettes infernales*, *allumettes chimiques*, and *Snellzünder*. The lucifers were followed by matches which could be ignited by friction on a suitable material fixed to the box holding the matches. The matches were tipped with a mixture of potassium chlorate, antimony sulphide, sulphur, and gum; the rubbing surface fixed on the box was coated with a mixture of potassium chlorate, red-lead, pumice-stone, and gum. Matches capable of being struck on the box came to be called *congreves*.

F. Dérosne is generally credited with having first tipped matches with a composition containing phosphorus which ignited by friction. This was about 1812; but with no marked commercial success. Between 1831 and 1833, there were several claimants for the substitution of phosphorus for antimony sulphide in the lucifer matches—*e.g.* C. Sauria of St. Lothair, France; J. F. Kammerer of Ludwigsburg, Germany; J. Irinyi, South Hungary; and J. S. Baggert of Stockholm, Sweden. There are numerous patents for modifications in the recipe—*e.g.* 1835, O. F. A. Trévani and J. Krutzler[4] recommended red-lead or manganese dioxide in place of potassium chlorate.

The manufacture of matches has been described by G. Gore,[5] W. H. Dixon, E. G. Clayton, etc. The common friction matches were made by cutting soft wood into the required shape by machinery. One end of the strip is dipped into some inflammable substance—paraffin or sulphur, and then into a paste made from yellow phosphorus, manganese dioxide, glue, and colouring matter. Other oxidizing agents can be used. The matches are then dried. The glue protects the phosphorus from oxidation, but by rubbing the head of the match on a rough surface, sufficient heat is generated to ignite the phosphorus in contact with the oxidizing agent. The burning phosphorus ignites the sulphur or paraffin, and this in turn fires the wood. Cotton threads dipped in paraffin are used in place of wood to form the so-called *wax vestas.* Numerous other suggestions have been made for the stems of matches. Various varnishes, collodion, and other preparations have been used for making the matches waterproof; and scenting ingredients—gum benzoin, frankincense, etc.—have been added to the varnishes. *Headless matches* are those in which the splint is soaked in some compound which easily gives up its oxygen. Patents for this were obtained by V. Simonet, H. Schwarz, S. Neuberg, S. L. Fog and A. G. Kirschner, C. C. Budde, G. A. Haffner, H. Huntingdon, etc.

In spite of the greatest care, the phosphorus disease was an ever-present menace in match factories using yellow phosphorus, and stringent regulations for the use of yellow phosphorus were introduced, followed by the complete prohibition of this agent in most civilized countries. The use of red phosphorus in place of yellow phosphorus was mentioned in a Swedish Government report by G. E. Pasch[6] in 1847; the process was tried in many countries, but did not succeed. The higher cost of the red phosphorus, and the unstable and dangerous nature of the mixtures employed, were largely responsible for this. Many of the advantages of the phosphorus, strike-anywhere matches were obtained by the use of phosphorus sesquisulphide, *i.e.* the tetritatrisulphide patented in 1898 by H. Sévène and E. D. Cahen; although C. Puschner, in 1860, used phosphorus sulphide in place of phosphorus. The use of scarlet phosphorus was patented by W. Muir and C. R. E. Bell in 1902; but it did not prove so efficacious as the sulphide, and it has been abandoned. Some light red phosphorus is, however, still in use in a few continental factories. Numerous other substitutes for phosphorus have been tried without success.

In 1855, R. Böttger suggested that friction matches could be made which would ignite only by friction on a specially prepared surface. The process was patented in England by F. May in 1865. The oxidizing agent—potassium chlorate, antimony sulphide, and glue—is put on the match stick, and red phosphorus, powdered glass, and glue on the box. These are the true safety matches. These matches have the disadvantage that they can be ignited only by friction on a prepared surface, or by quickly rubbing them on a smooth non-conducting surface like glass or slate; but they are not liable to ignite by accidental friction. Numerous patents have been taken for safety matches free from phosphorus—*e.g.* the oxidizing agent may be potassium chlorate, dichromate, etc., and the red phosphorus on the box was replaced by antimony oxysulphide and sulphur.

§ 39. Phosphorus Oxysulphides; the Thiophosphoric Acids and their Salts

Compounds have been reported with part of the oxygen in phosphorus pentoxide replaced by sulphur. For example, A. Besson[1] said that **phosphorus dioxytrisulphide**, $P_2O_2S_3$, is formed when hydrogen sulphide is dissolved in phosphorus oxychloride at 0°, and the soln. is allowed to remain in a closed vessel, a yellowish-white, amorphous precipitate forms in about 24 hours, and after many weeks small, acicular crystals also separate. The amorphous product can be crystallized by dissolving it in phosphorus oxychloride in a closed vessel at 150°. When heated at 150°, the oxysulphide yields a sublimate of pentasulphide, and if heated in a vacuum at 200° for several hours, it completely decomposes into pentoxide and pentasulphide. It is slowly decomposed by water and moist air with liberation of hydrogen sulphide, burns in air or oxygen, and is violently oxidized by nitric acid.

T. E. Thorpe and A. E. H. Tutton reported **phosphorus trioxydisulphide**, $P_2O_3S_2$, to be formed when a mixture of sulphur and phosphorous oxide is heated at 160° in a sealed tube, or in an atm. of nitrogen or carbon dioxide: $P_4O_6+4S=P_4O_6S_4$. The colourless rectangular prisms are probably tetragonal terminated by a basal plane. The trioxydisulphide has a vap. density 11·8–12·5, air unity; this is in agreement with the formula required for $P_4O_6S_4$. The compound melts at about 102°, and boils without decomposition at 295°. The compound dissolves readily in twice its vol. of carbon disulphide from which soln. it can be crystallized unchanged; it also dissolves in benzene, but there is a chemical reaction with that solvent. It decomposes rapidly in air, and then smells of hydrogen sulphide, it is decomposed by water: $P_4O_6S_4+6H_2O=4HPO_3+4H_2S$.

Compounds are known in which all or part of the oxygen of the acids of phosphorus has been replaced by sulphur. Even if the parent acid is not known, salts have been obtained. Representatives of the following thiophosphorous acids have been so obtained : *monothiophosphorous acid*, $H_2(HPSO_2)$; *dithiophosphorous acid*, $H_2(HPS_2O)$; and *trithiohydrophosphorous acid*, $H_2(HPS_3)$, in which all three hydrogen atoms are replaced by a metal salt of *thiopyrophosphorous acid*, $H_4P_2S_5$, have also been reported. Representatives of *hypothiophosphoric acid*, $H_4P_2S_6$, have been obtained, as well as of *monothiophosphoric acid*, H_3PSO_3 ; of *dithiophosphoric acid*, $H_3PS_2O_2$; of *trithiophosphoric acid*, H_3PS_3O ; of *tetrathiophosphoric acid*, or *orthothiophosphoric acid*, H_3PS_4 ; of *thiopyrophosphoric acid*, $H_4P_2S_7$; of *pentathiopyrophosphoric acid*, $H_4P_2S_5O_2$; and of *trithiopyrophosphoric acid*, $H_4P_2S_3O_4$.

L. Ferrand [2] prepared a series of **thiophosphites** by heating the metals with the calculated proportions of red phosphorus and sulphur in sealed tubes. These compounds are represented as derivatives of **thiophosphorous acid,** H_3PS_3. L. Ferrand was unable to prepare *cupric thiophosphite*, $Cu_3(PS_3)_2$, in this way because the products were sulphur, phosphorus tetritahexasulphide, and cupric thiophosphate ; but he did obtain **cuprous thiophosphite,** Cu_3PS_3, by heating at 450°, in an atm. of carbon dioxide to constant weight, a mixture of 3 parts of cuprous sulphide and 4 of phosphorus pentasulphide ; and also by heating, in the absence of air and at a red-heat for 20–24 hrs., a mixture of cupric sulphide and red phosphorus ; or a mixture of copper, phosphorus, and sulphur. The orange powder may have a metallic lustre, and it consists of octahedral crystals. It decomposes at a red-heat in an inert gas, and it forms cupric oxide when heated in air. It is not attacked by water, boiling soda-lye, or boiling conc. hydrochloric acid ; fuming nitric acid decomposes it slowly in the cold ; ordinary nitric acid, and aqua regia attack it vigorously ; and with hot sulphuric acid it forms sulphur dioxide. L. Ferrand obtained a black mass of **silver thiophosphite,** Ag_3PS_3, by heating a mixture of eq. quantities of the constituent elements. The black mass is very resistant towards acids ; he obtained a similar product, Ag_4PS_3, in an analogous manner. By heating a mixture of the component elements, pale yellow, hexagonal crystals of zinc thiophosphate, $Zn_3(PS_3)_2$, can be obtained; the salt is rapidly decomposed by moist air, and by acids. L. Ferrand did not make *mercurous thiophosphite*, Hg_3PS_3, but he obtained **mercuric thiophosphite,** $Hg_3(PS_3)_2$, from the component elements at a red-heat. E. Baudrimont obtained it from a mixture of phosphorus tetritahexasulphide and mercuric sulphide. According to L. Ferrand, the orange-red crystalline mass cannot be sublimed, but it melts in vacuo without decomposition; on the other hand, E. Baudrimont said that it can be sublimed with partial decomposition ; and that when heated the salt becomes black, and red on cooling. L. Ferrand found the salt is attacked by moist air ; and is scarcely affected by cold nitric acid, but decomposed completely by the hot acid. Long, white crystals of **aluminium thiophosphite,** $Al_3(PS_3)_2$, or perhaps $AlPS_3$, are obtained by heating a mixture of the component elements. The salt is very unstable in air, and is decomposed by water and acids with the evolution of hydrogen sulphide. A black powder of **chromium thiophosphite,** $Cr_3(PS_3)_2$, was obtained in a similar manner. It consists of small hexagonal crystals with a metallic lustre. The salt is stable in moist air ; is easily attacked by hot, conc. nitric acid, and by aqua regia ; and is decomposed by fusion with a mixture of potassium hydroxide and chlorate, or by boiling with soda-lye. A black, crystalline mass of small plates of **ferrous thiophosphite,** $Fe_3(PS_3)_2$, was obtained in a similar way ; it is stable in moist air. A dark brown mass of **nickel thiophosphite,** $Ni_3(PS_3)_2$, was obtained from its component elements. It is decomposed in a few hours by moist air ; and is attacked by hot water, nitric acid, and by aqua regia.

G. Lemoine found that phosphorus tetritatrisulphide is rapidly decomposed by a soln. of sodium hydroxide with the evolution of hydrogen mixed with phosphine, and the separation of a small quantity of free phosphorus. The evaporation of the soln. in vacuo yields crystals of **sodium monothiohydrophosphite,** $Na_2(HPSO_2).2$ or $2\frac{1}{2}H_2O$.

Again, when a dil. soln. of sodium hydroxide and an excess of tetritatrisulphide, at 0°, is evaporated in vacuo, hydrogen sulphide is evolved and sodium hydrophosphite is alone deposited; if the sodium hydroxide be in excess, and the filtered soln. is left over sulphuric acid and phosphorus pentoxide for about 5 months, prismatic crystals of sodium sulphide, $Na_2S.5H_2O$, are deposited; about a month later, crystals of the monothiohydrophosphite appear; and after 4 months, crystals of **sodium monothiophosphite,** $Na_3(PSO_2).2H_2O$, are formed in which all three hydrogen atoms of the monothiophosphorous acid have been replaced by a base—a mixed sodium monothio- and dithio-phosphite was also obtained. When the tetritatrisulphide acts on sodium hydrosulphide, hydrogen sulphide and phosphine are evolved, and the soln., on evaporation in vacuo, yields crystals of **sodium dithiohydrophosphite,** $Na_2(HPS_2O).2\frac{1}{2}H_2O$.

When an excess of phosphorus tetritatrisulphide is gradually added in small portions at a time to ammonium hydrosulphide at 0°, and the liquid allowed to stand for about 15 days, crystals of ammonium hydrophosphite are formed, along with small quantities of a sulphur compound. If the mother-liquor be evaporated in vacuo, hydrogen sulphide is copiously evolved, and in about 6 or 7 months, crystals of **ammonium monothiohydrophosphite,** $(NH_4)_2(HPSO_2).H_2O$, are deposited. When this salt is dissolved in water, and the soln. evaporated in vacuo, partial hydrolysis occurs, and what is probably a mixture of thiohydrophosphite and hydrophosphite, $2(NH_4)_2O.P_2O_2S.6H_2O$, separates out. The ammonium thiohydrophosphites may also have some hydrogen sulphide in place of water of crystallization. All these salts are of the same type; sulphur replaces oxygen in phosphorous acid; and in some of them the water of crystallization, and even the water of constitution of the phosphorous acid, has been replaced by hydrogen sulphide. In the latter case, the salts lose hydrogen sulphide at ordinary temperatures. All the compounds give precipitates with most of the metallic salts. With lead acetate, they give a precipitate of the corresponding **lead thiohydrophosphite,** which has a colour varying from yellow to red. It soon decomposes into lead sulphide and phosphorous acid. With hydrochloric acid, the solid compounds give off hydrogen sulphide. When heated to 200°–240°, they lose hydrogen sulphide, but retain a portion of their sulphur, even after prolonged ignition. When their aqueous solutions are boiled, all the sulphur is given off as hydrogen sulphide, an alkaline phosphite being formed. The existence of these compounds affords further proof of the analogy between oxygen and sulphur.

J. J. Berzelius[3] reported **silver thiopyrophosphite,** $Ag_4P_2S_5$, to be formed by heating a mixture of finely divided silver, phosphorus, and sulphur in an atm. of hydrogen. There is a vigorous reaction, and much phosphorus is vaporized. The grey mass forms a pale yellow powder. The salt readily dissolves in nitric acid without the separation of sulphur.

C. Friedel[4] prepared a series of **thiohypophosphates** by heating to redness a mixture of the metal, phosphorus, and sulphur in a sealed tube. L. Ferrand also obtained some of those salts in a similar way, and also by heating to 400° a mixture of the metal sulphide with an excess of phosphorus tetritahexasulphide or tetritadecasulphide. The result with copper in both cases is to produce **copper thiohypophosphate,** $Cu_2P_2S_6$. The yellowish-brown powder contains some needle-like crystals. C. Friedel obtained **silver thiohypophosphate,** $Ag_4P_2S_6$, in a similar way; and also a pale yellow mass of **zinc thiohypophosphate,** $Zn_2P_2S_6$, consisting of pale yellow hexagonal plates of sp. gr. 2·2. The salt is insoluble in water, but is decomposed by boiling water with the evolution of hydrogen sulphide; it is not attacked by hydrochloric or nitric acid, but is decomposed by aqua regia. L. Ferrand said that it is attacked by acetic acid with the separation of sulphur. A mass of orange-yellow crystals of **cadmium thiohypophosphate,** $Cd_2P_2S_6$, was obtained by L. Ferrand by heating a mixture of the component elements at a red-heat. The salt is stable in dry air, but is decomposed by moist air, and by cold nitric acid. C. Friedel prepared a sulphur-yellow crystalline mass of **mercuric**

thiohypophosphate, $Hg_2P_2S_6$, from a mixture of the elements heated in a sealed glass tube. The salt gradually blackens when exposed to light; and in the presence of an excess of phosphorus sulphide it can be sublimed; but it is decomposed when heated alone. The salt is slowly decomposed by boiling water with the evolution of hydrogen sulphide; it is rapidly attacked by potash-lye with the separation of mercuric sulphide. C. Friedel made brownish-white **aluminium thiohypophosphate,** $Al_4(P_2O_6)_3$, by heating a mixture of the constituent elements in a sealed tube. The white crystal plates are transparent; they rapidly become matte when exposed to air, and are decomposed by water with the evolution of hydrogen sulphide. C. Friedel made **stannic thiohypophosphate,** SnP_2S_6, by the same method; **stannous thiohypophosphate,** $Sn_2P_2S_6$, seems to be formed in a similar way using the right proportions of the three elements. The yellowish-brown mass of either salt is decomposed by boiling water with the evolution of hydrogen sulphide. C. Friedel, and L. Ferrand prepared **lead thiohypophosphate,** $Pb_2P_2S_6$, by the methods indicated above. The orange-yellow crystalline mass is not attacked by water. L. Ferrand reported **chromium thiohypophosphate,** $Cr_2P_2S_6$, to be formed by heating a mixture of the component elements to redness for 24 hrs. The black powder consists of hexagonal plates; it is insoluble in nitric acid; almost insoluble in aqua regia; and attacked by molten sodium carbonate. C. Friedel prepared **iron thiohypophosphate,** $Fe_2P_2S_6$, in a similar way. It forms brilliant, greyish-black, hexagonal lamellæ resembling those of graphite or specular hæmatite. The lamellæ, when very thin, are brown by transmitted light, and have no action on parallel polarized light. The compound is attacked by nitric acid, but more easily by a mixture of the acid with potassium chlorate. L. Ferrand prepared **nickel thiohypophosphate,** $Ni_2P_2S_6$, by heating a mixture of the component elements to redness for 14 hrs. It forms brilliant, grey, hexagonal crystals of sp. gr. 2·4. It is stable towards moist air, and is not affected by water or cold acids; aqua regia attacks it slowly; it is decomposed by a mixture of nitric acid and potassium chlorate.

L. Ferrand[5] prepared some normal **thio-orthophosphates** by the action of phosphorus tetritahexasulphide, or tetritadecasulphide on the metal sulphide at 400°; and E. Glatzel, by heating phosphorus tetritadecasulphide with the metal chloride: $3MCl_2+P_2S_5=PSCl_3+M_3PS_4+3Cl$; or sulphide: $3M_2S+P_2S_5=2M_3PS_4$. All these thiophosphates burn with a livid flame when heated in air; they are all insoluble in water, alcohol, ether, benzene, carbon disulphide, and acetic acid; some are decomposed by sulphuric or hydrochloric acid with the evolution of hydrogen sulphide; but they are not affected by aq. ammonia, or potash-lye; boiling nitric acid, aqua regia, or nitric acid and bromine easily decomposes these salts; and they yield sulphur dioxide when heated with conc. sulphuric acid. According to F. Ephraim and E. Majler, when sodium thiophosphate, Na_3PS_4, is treated with the solutions of sulphides of other metals, reaction takes place either according to the equation: $2Na_3PS_4+3M_2S+2H_2O=2M_3PS_3O+3Na_2S+2H_2S$, or according to the equation: $2Na_3PS_4+3M_2S+4H_2O=2M_3PS_2O_2+3Na_2S+4H_2S$. In no case is the tetrathiophosphate of the second metal formed, owing to hydrolysis by the water.

E. Glatzel was unable to make normal **ammonium thiophosphate,** $(NH_4)_3PS_4$, by heating phosphorus sulphide with ammonium chloride; nor did he obtain the normal **sodium thiophosphate,** Na_3PS_4, by heating a mixture of a mol of phosphorus sulphide with 3 mols of sodium chloride; but he did obtain **octohydrated sodium thiophosphate,** $Na_3PS_4.8H_2O$, by fusing sodium monosulphide and phosphorus tetritadecasulphide: $3(Na_2S.9H_2O)+P_2S_5=2(Na_3PS_4.8H_2O)+11H_2O$. A conc. aq. soln. of the product deposits crystals of the salt. The salt cannot be recrystallized from water without decomposition. The pale yellow or colourless crystals, acicular or tabular, belong to the monoclinic system. When heated, the salt decomposes with the loss of the water of crystallization; acids decompose the salt with the evolution of hydrogen sulphide; with conc. sulphuric acid or conc. nitric acid, there is a separation of sulphur; with soln. of the metal salts, coloured precipitates or coloured soln. are obtained. He obtained **potassium thiophosphate,** K_3PS_4, contaminated with some phosphorus tetritadecasulphide, and potassium chloride. The yellow salt is fusible, and freezes to a crystalline mass. It dissolves in water or dil. acid with the evolution of hydrogen sulphide; but dissolves in aq. ammonia or potash-lye without developing a gas.

E. Glatzel made **cuprous thiophosphate,** Cu_3PS_4, from cuprous chloride and the vapour of phosphorus sulphide; and L. Ferrand, by treating copper sulphophosphides with the vapour of phosphorus sulphide; by the action of phosphorus tetritadecasulphide on cuprous sulphide; by heating cuprous sulphide, phosphorus, and sulphur to redness; by heating cuprous thiophosphite in vacuo, and washing the product with carbon disulphide, alcohol, and finally with ether; and also by heating a mixture of the elements to redness. The yellowish-brown or reddish-yellow powder consists of microscopic crystals, which burn when heated in air. The salt is decomposed by boiling nitric or sulphuric acid, aqua regia, or a mixture of nitric acid and bromine; but is not affected by aq. ammonia, or alkali-lye. Attempts to make **cupric thiophosphate,** $Cu_3(PS_4)_2$, always gave the cuprous salt. E. Glatzel prepared **silver thiophosphate,** Ag_3PS_4, from silver chloride and phosphorus tetritadecasulphide. The sulphur-yellow crystalline mass readily fuses to an orange-red or greyish-black mass, which when triturated gives a yellow powder. It is blackened when treated with alkali-lye. It is insoluble in water, organic solvents, and in acetic, hydrochloric, dil. sulphuric, and nitric acids, but it gives off sulphur dioxide when heated with conc. sulphuric acid, and yields silver chloride when treated with aqua regia.

Attempts to make **calcium, strontium, and barium thiophosphates** by the general methods were not successful. E. Glatzel obtained **zinc thiophosphate,** $Zn_3(PS_4)_2$, from the dry chloride and phosphorus tetritadecasulphide. The small, colourless, or white crystal plates burn with a livid flame in air without melting. The salt is decomposed by nitric acid and bromine, and by aqua regia; it is insoluble in water, aq. ammonia, and alkali-lye. Small white plates of the corresponding **cadmium thiophosphate,** $Cd_3(PS_4)_2$, was prepared in a similar manner, and its properties were similar to those of the zinc salt. Attempts to make mercurous thiophosphate, Hg_3PS_4, always yielded **mercuric thiophosphate,** $Hg_3(PS_4)_2$, which is best obtained from mercuric sulphide and phosphorus tetritadecasulphide. The red crystalline mass looks like potassium dichromate; it burns with a livid flame, without melting. It is insoluble in water, organic solvents, aq. ammonia, and in acetic, hydrochloric, nitric, and dil. sulphuric acids. Conc. nitric acid, and aqua regia have no action; hot conc. sulphuric acid gives sulphur dioxide; it is readily dissolved by a mixture of nitric acid and bromine; and is blackened by potash-lye.

E. Glatzel prepared **thallous thiophosphate,** Tl_3PS_4, by a method analogous to that used for the mercuric salt. The yellow crystalline mass melts and burns with a green flame; it is insoluble in water, organic solvents, and acetic acid; it is decomposed when heated with dil. sulphuric or hydrochloric acid; it dissolves in warm nitric acid, and in aqua regia; it gives sulphur dioxide when heated with conc. sulphuric acid; it is not attacked by aq. ammonia; and blackens when treated with alkali-lye. E. Glatzel obtained **stannous thiophosphate,** $Sn_3(PS_4)_2$, by the reaction: $3SnCl_2+2P_2S_5=2PSCl_3+Sn_3(PS_4)_2$, as a grey, crystalline mass, which burns in air. It is insoluble in water, organic solvents, and acetic, dil. hydrochloric and sulphuric acids; when heated with conc. sulphuric acid it gives sulphur dioxide; and it is decomposed by nitric acid and bromine, aqua regia, alkali-lye, and aq. ammonia. Attempts to make **stannic thiophosphate,** $Sn_3(PS_4)_4$, were nugatory. A grey crystalline mass of **lead thiophosphate,** $Pb_3(PS_4)_2$, was prepared by the method employed for the stannous salt. Its properties are similar.

E. Glatzel obtained a grey, crystalline mass of **arsenic thiophosphate,** $AsPS_4$, by heating a mixture of arsenic trisulphide and phosphorus tetritadecasulphide.

The salt melts easily and can be distilled without decomposition; it burns with a livid flame when heated in air; it is insoluble in water and organic solvents; hydrochloric acid has no action; dil. sulphuric acid decomposes it with the evolution of hydrogen sulphide, and when heated with conc. sulphuric acid, it yields sulphur dioxide. It is dissolved by nitric acid, aq. ammonia, and alkali-lye. E. Glatzel prepared **antimony thiophosphate,** $SbPS_4$, by the action of phosphorus tetritadecasulphide on antimony trisulphide or trichloride. Forty grms. of the finely-powdered phosphorus sulphide are mixed with 80 grms. of antimony trichloride by shaking in a retort, and warmed for one hour on the sand-bath with the neck of the retort pointing upwards; when the reaction is ended, the phosphorus thiochloride and excess of antimony trichloride are distilled off. The antimony thiophosphate which remains in the retort is bright yellow; it melts when the temp. is raised, and solidifies on cooling in radiating, fibrous crystals of brilliant, silky lustre; when ground up, it yields a straw-coloured felted mass which smells of hydrogen sulphide, is insoluble in water, alcohol, ether, carbon bisulphide, hydrochloric acid, dil. sulphuric acid, benzene, and acetic acid, but is decomposed when boiled with conc. nitric acid, aqua regia, conc. sulphuric acid, and soln. of potassium or sodium hydroxide, and burns with a pale flame when heated in the air. When heated at its m.p. for some time, decomposition takes place, a part of the phosphorus sulphide distils off, and a ruby-red, amorphous mass remains. E. Glatzel made **bismuth thiophosphate,** $BiPS_4$, from the chloride: $BiCl_3+P_2S_5=BiPS_4+PSCl_3$. The dark grey, crystalline mass burns with a livid flame when heated in air; it is insoluble in water, and in organic solvents. It is decomposed by boiling hydrochloric acid with the evolution of hydrogen sulphide; hot conc. sulphuric acid gives sulphur dioxide; dil. sulphuric acid has no action; nitric acid and aqua regia decompose it with the separation of sulphur; and it is decomposed by aq. ammonia, and alkali-lye.

E. Glatzel prepared **manganese thiophosphate,** $Mn_3(PS_4)_2$, from manganese sulphide and phosphorus tetradecasulphide. The greenish plates burn with a yellowish-white flame, without melting when heated in air. When heated to a high temp., phosphorus sulphide distils off, leaving manganese sulphide. The salt is insoluble in water, and in organic solvents; it is not attacked by hydrochloric acid, it is easily decomposed by nitric acid, and by aqua regia with the separation of sulphur; dil. sulphuric acid is without action; and hot, conc. sulphuric acid furnishes sulphur dioxide. Attempts to make **ferric thiophosphate** were a failure because the reaction proceeds: $3Fe_2Cl_6+2P_2S_5=3FeCl_2+3FeS_2+4PSCl_3$, and not $2FeCl_3+2P_2S_5=2PSCl_3+Fe_2(PS_4)_2$. E. Glatzel obtained **ferrous thiophosphate,** $Fe_3(PS_4)_2$, from ferrous sulphide, not the chloride. The black crystalline plates burn in air with a livid flame, without melting. The salt is insoluble in water, organic solvents, and in acetic, dil. sulphuric and hydrochloric acids; it is decomposed by nitric acid, and aqua regia; and it is decomposed by hot, conc. sulphuric acid with the evolution of sulphur dioxide. Aq. ammonia, and alkali-lye have no action. E. Glatzel obtained **nickel thiophosphate,** $Ni_3(PS_4)_2$, by the reaction: $3NiCl_2+2P_2S_5=Ni_3(PS_4)_2+2PSCl_3$. The dark brown, crystalline plates burn in air without melting, and are decomposed at a high temp. giving off phosphorus sulphide and leaving a residue of nickel sulphide. The salt is insoluble in water, organic solvents, and acetic, hydrochloric, and dil. sulphuric acids; it is decomposed by nitric acid, aqua regia, and hot conc. sulphuric acid. Warm aq. ammonia, or alkali-lye gave a green or brown coloration.

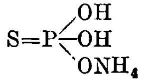
C. Kubierschky[6] prepared a series of **oxythiophosphates** with only part of the oxygen of the normal phosphates replaced by sulphur. He said that acids decompose all thiophosphates; hydrogen sulphide is evolved, and, in some cases, sulphur separates. Monothiophosphates give white precipitates with calcium, barium, and strontium salts, the dithiophosphates with barium and strontium salts, and the trithiophosphates with barium salts only. All thiophosphates yield precipitates with cadmium, copper, silver, and mercurous salts, which decompose after a time, forming the sulphides of the metals. With a dithiophosphate, manganese sulphate gives a green coloration, which becomes darker on shaking; a further addition of manganese sulphate gives a dark green precipitate, which gradually becomes white, but on shaking changes back to green. Ferrous salts give a dirty greyish-green precipitate with monothiophosphates. Ferric salts give red colorations with all thiophosphates, from which solutions, on boiling, ferrous sulphide separates out. An excess of ferric chloride gives a precipitate with monothiophosphates only, which, on continued boiling, is decomposed with the production of iron phosphate and sulphuretted hydrogen. A soln. of a thiophosphate containing a small quantity of an alkaline sulphide gives an intense green coloration with ferric chloride. Cobalt sulphate gives with a monothiophosphate a blue precipitate soluble in excess of the latter to a blue soln.; the dithiophosphates give dirty green precipitates, soluble in excess of the thiophosphate to green soln.; the trithiophosphates give a red to a brown coloration. In each case, boiling produces a precipitate of cobalt sulphide. Nickel sulphate in excess gives a light green precipitate with monothiophosphates, and a dirty blue precipitate with a dithiophosphate. Many of these coloured soln., produced as above described, exhibit characteristic absorption-spectra. Nitric acid decomposes all thiophosphates with a precipitation of sulphur; potassium permanganate, dichromate, and ferricyanide, are reduced by thiophosphates, sulphur separating out in each case. Monothiophosphates decolorize iodine soln. with an immediate precipitation of sulphur, whereas in the case of the di- and tri-thiophosphates the separation of sulphur takes place only after some time or on boiling.

According to C. Kubierschky, **trithiophosphoric acid,** H_3PS_3O, or $(HS)_3PO$, cannot be isolated from its salts because the liberated acid immediately decomposes with the separation of sulphur and the evolution of hydrogen sulphide. C. Kubierschky did not succeed in isolating **sodium trithiophosphate,** Na_3PS_3O, but a soln. of the salt is produced when phosphorus tetritadecaphosphate reacts with a soln. of sodium hydrosulphide below 20°. A. Stock, however, obtained the secondary sodium salt, **sodium hydrotrithiophosphate,** $(NaS)_2(HS)PO$, by the action of sodium ethoxide on the tertiary ammonium salt. It is easily soluble in water, and in methyl alcohol, but decomposes when heated with the evolution of hydrogen sulphide. A. Stock and co-workers prepared **ammonium trithiophosphate,** $PO(SNH_4)_3.H_2O$, by the action of water on ammonium imidotrithiophosphate; it slowly loses water in a vacuum desiccator, and the aq. soln. gives precipitates of various salts when added to soln. of the metal salts. A. Stock obtained **copper trithiophosphate** from a soln. of copper sulphate and ammonium trithiophosphate; and **silver trithiophosphate** from an ammoniacal soln. of silver nitrate. F. Ephraim and E. Majler obtained **barium trithiophosphate,** $Ba_3(PS_3O)_2.20H_2O$, from normal sodium thiophosphate and a soln. of barium sulphide. The salt is stable when dry, but is decomposed by water or dil. acids with the evolution of hydrogen sulphide. Conc. nitric acid dissolves it, oxidizing the sulphur to sulphuric acid. Unsuccessful attempts were made to prepare **strontium trithiophosphate,** and **calcium trithiophosphate**; A. Stock, however, did make the calcium salt from a soln. of the ammonium salt and a soln. of a calcium salt. F. Ephraim and E. Majler prepared **magnesium trithiophosphate,** $Mg_3(PS_3O)_2.20H_2O$, by the action of normal sodium thiophosphate on a soln. of magnesium hydrosulphide. It is precipitated by alcohol from the aq. soln. in the form of white needles. It is decomposed by water and dil. acids. A. Stock obtained white precipitates of **zinc trithiophosphate** from the ammonium salt and a soln. of zinc sulphate; **cadmium trithiophosphate** from a soln. of cadmium sulphate; **mercuric trithiophosphate** from a soln. of mercuric chloride; **lead trithiophosphate,** $Pb_3(PS_3O)_2$, from lead nitrate; **bismuth trithiophosphate** from bismuth nitrate; and **chromium trithiophosphate** from a soln. of chromium sulphate.

C. Kubierschky found that when **dithiophosphoric acid,** $H_3PS_2O_2$, is liberated from its salts, the acid immediately decomposes with the separation of sulphur and the evolution of hydrogen sulphide. C. Kubierschky prepared **ammonium dithiophosphate,** $(NH_4)_3PS_2O_2.2H_2O$, by the action of aq. ammonia on phosphorus tetritadecasulphide; the soln. gives acicular crystals which effloresce, and at the same time decompose with the separation of sulphur. A. Stock obtained it by adding alcohol to a soln. of ammonium imidotrithiophosphate until it appears turbid, then a few drops of water until the soln. clarifies, and then pour a layer of alcohol over the soln. and allow it to stand 24 hrs. This salt is also produced when normal ammonium trithiophosphate is treated with water at ordinary temp. C. Kubierschky said that the colourless needles effloresce in air and sulphur is separated. He also prepared **sodium dithiophosphate,** $Na_3PS_2O_2.11H_2O$, by dissolving in water the mixture of thiophosphates obtained by adding a mol of powdered phosphorus tetritadecasulphide to a moderately conc. soln. of 6 mols of sodium hydroxide, and heating the soln. at 50°–55°, until all trithiophosphate has been destroyed, as shown by a drop of the soln. giving a green instead of a yellow or brown coloration with a soln. of cobalt sulphate. The soln. is now cooled, as further heating converts the dithiophosphate into the monothiophosphate, and alcohol is added; a precipitate of almost pure sodium dithiophosphate is then formed which may be purified by crystallization from water. It forms colourless, six-sided crystals, melting at 45°–46°; it decomposes into monothiophosphate or phosphate and sulphur, at temperatures a little above the ordinary. The corresponding **lithium dithiophosphate,** $Li_3PS_2O_2$, is a soluble salt by the action of ammonium dithiophosphate on a lithium salt soln. **Potassium dithiophosphate,** $K_3PS_2O_2$, could be obtained only in soln. C. Kubierschky obtained precipitates of **copper dithiophosphate** by adding sodium dithiophosphate to a soln. of copper sulphate; and **silver dithiophosphate** was obtained in an analogous way. Unstable **calcium dithiophosphate,** $Ca_3(PS_2O_2)_2.nH_2O$, was obtained in needle-like crystals by the rapid evap. of the aq. soln. The aq. soln. is decomposed by alcohol. When a soln. of sodium dithiophosphate is added to one of barium chloride, **barium dithiophosphate,** $Ba_3(PS_2O_2)_2.8H_2O$, is formed as a white precipitate. F. Ephraim and E. Majler prepared barium dithiophosphate, $Ba_3(PS_2O_2)_2.18H_2O$, by the action of normal sodium thiophosphate on a soln. of barium hydrosulphide. C. Kubierschky obtained **strontium dithiophosphate,** and calcium dithiophosphate by the method employed for the barium salt. Unstable **magnesium dithiophosphate,** $Mg_3(PS_2O_2)_2.nH_2O$, was obtained by the process employed for the calcium salt. It is very soluble in water. When a soln. of sodium dithiophosphate is added to one of magnesium sulphate in the presence of ammonia, **ammonium magnesium dithiophosphate,** $MH_4MgPS_2O_2.6H_2O$, is formed. It closely resembles the magnesium salt. C. Kubierschky found that sodium dithiophosphate precipitates **mercurous dithiophosphate** from soln. of mercurous salts; an excess of the sodium salt with mercuric chloride gives when boiled a black precipitate, but with an excess of mercuric chloride, the precipitate remains white when boiled. A green soln. is obtained with manganese sulphate; greenish soln. with ferrous sulphate; red soln. with ferric salts; bluish-violet soln. with nickel sulphate; and a dirty green precipitate—**cobalt dithiophosphate**—with cobalt sulphate which with an excess of the dithiophosphate becomes bright green.

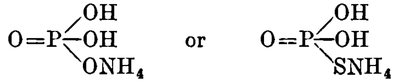
According to C. A. Wurtz, **monothio-orthophosphoric acid,** H_3PSO_3, is liberated from its salts by the feeblest of acids, but it is immediately hydrolyzed: $H_3PSO_3+H_2O=H_3PO_4+H_2S$, and, added A. Michaelis, some phosphorus acid and sulphur are formed at the same time. C. Kubierschky prepared **sodium monothiophosphate,** $Na_3PSO_3.12H_2O$, from the mixture employed for the preparation of the dithiophosphate. The soln. was treated with alcohol to precipitate the thiophosphates. The precipitated thiophosphates are dissolved in water, and the soln. heated at 90° for some time, in order to decompose the dithiophosphate into monothiophosphate and from this soln., on cooling, the latter separates out in white six-sided tablets, melting at 60°. This salt is identical with that obtained by C. A. Wurtz by the action of phosphorus thiochloride on sodium hydroxide:

$PSCl_3+6NaOH=Na_3PSO_3+3NaCl+3H_2O$. T. E. Thorpe and J. W. Rodger obtained it likewise from the thiophosphoryl fluoride. B. Rathke obtained it by C. Kubierschky's process. The hexagonal crystals were examined by F. de la Provostaye. C. Kubierschky said the crystals melt at 60°, and readily form undercooled soln. C. A. Wurtz found that the crystals dissolve readily in hot water and are deposited on cooling; the aq. soln. is alkaline. According to C. A. Wurtz, chlorine, bromine, iodine, or nitric acid reacts according to the type equation: $Na_3PSO_3+Cl_2+H_2O=NaH_2PO_4+2NaCl+S$—*vide supra*, general reactions of the thiophosphates. C. Kubierschky could obtain **potassium monothiophosphate,** K_3PSO_3, only in soln.; and similarly with normal or tertiary **ammonium monothiophosphate,** $(NH_4)_3PSO_3$. A. Stock obtained the tertiary salt by the action of aq. ammonia on the primary salt—*vide infra*. It occurs as a bone-white, crystalline powder which loses 2 mols of ammonia when gently heated or dried over sulphuric acid in vacuo. It gives precipitates with soln. of the metal salts—*vide supra*. A. Stock prepared primary ammonium monothiophosphate or **ammonium dihydromonothiophosphate** by the action of water on imidotrithiophosphoric acid: $NHP(SH)_3+3H_2O=2H_2S+PO(OH_2)(SNH_4)$. By repeated soln. in water, and precipitation with alcohol, a colourless salt is obtained. When the salt is heated it forms hydrogen sulphide and ammonium metaphosphate. It is not clear if the ammonium radicle replaces the hydrogen of an OH-group. F. D. Dodge prepared ammonium dihydromonothiophosphate, $(NH_4O)(OH)_2PS$, or $(NH_4)H_2PSO_3$, in which the sulphur is associated with the phosphorus atom:



$$\mathrm{S{=}P}\begin{matrix}\mathrm{OH}\\ \mathrm{OH}\\ \mathrm{ONH_4}\end{matrix}$$

F. D. Dodge's salt.



$$\mathrm{O{=}P}\begin{matrix}\mathrm{OH}\\ \mathrm{OH}\\ \mathrm{ONH_4}\end{matrix} \quad \text{or} \quad \mathrm{O{=}P}\begin{matrix}\mathrm{OH}\\ \mathrm{OH}\\ \mathrm{SNH_4}\end{matrix}$$

A. Stock's salt.

The former is deposited in yellow crystals, mixed with sulphur; when acetoxime is treated with phosphorus pentasulphide in carbon bisulphide soln.; the insoluble product extracted with alcohol; and the alcoholic soln. heated to boiling; the compound separates from cold water in large, transparent, seemingly monoclinic prisms, melts at 146°–150° with decomposition, and is readily soluble in water, but only sparingly in alcohol, and insoluble in ether and carbon bisulphide. It decomposes carbonates, gives a colourless precipitate with lead acetate, and is decomposed by hot dilute nitric acid with separation of sulphur and formation of phosphoric acid; it is also decomposed by mercuric oxide, the filtrate from the precipitated mercury sulphide giving all the reactions of phosphoric acid.

C. A. Wurtz precipitated **copper monothiophosphate,** $Cu_3(PSO_3)_2$, from a copper salt soln. by adding sodium dithiophosphate. The salt is very unstable. He also obtained **silver monothiophosphate** in an analogous way. C. A. Wurtz, and C. Kubierschky obtained **calcium, strontium, and barium monothiophosphates** in a similar way from a soln. of a salt of the alkaline earth and sodium monothiophosphate; **magnesium monothiophosphate,** $Mg_3(PSO_3)_2.20H_2O$, was also prepared as a white crystalline precipitate on adding a soln. of the sodium salt to one of magnesium sulphate; and **ammonium magnesium monothiophosphate,** $(NH_4)MgPSO_3.9H_2O$, was obtained by a process analogous to that employed for the dithiophosphate. C. Kubierschky obtained precipitates of **cadmium monothiophosphate,** and **mercurous monothiophosphate** by adding the sodium salt to a soln. of a cadmium or mercurous salt; with a little mercuric chloride the precipitate is black; while **lead monothiophosphate** obtained in a similar way is white, but it soon becomes black by the separation of lead sulphide. Soln. of manganese sulphate give **manganese monothiophosphate**; and a ferrous salt soln. gives **ferrous monothiophosphate**; and with a ferric salt, a red soln. is obtained which decomposes with the separation of sulphur when boiled. C. A. Wurtz, and C. Kubierschky also obtained a blue precipitate of **cobalt monothiophosphate,** and green **nickel monothiophosphate,** both of which become black with boiling soln.

L. Ferrand prepared a series of thiopyrophosphates by heating the metals with the required proportions of sulphur and phosphorus in a sealed tube. In the case of **cuprous thiopyrophosphate,** $Cu_4P_2S_7$, L. Ferrand heated a mixture of the constituent elements to redness; and also a mixture of cuprous sulphide, sulphur, and phosphorus in a sealed tube at a red-heat. The blue, crystalline mass is red in transmitted light; when heated in air, it forms cupric sulphide and phosphorus pentoxide, and at a dark red-heat cuprous oxide. Hot sodium hydroxide decomposes it, forming cuprous sulphide; with hot sulphuric acid it forms sulphur dioxide; and it is not attacked by cold sulphuric acid or hot hydrochloric acid. J. J. Berzelius reported **cupric thiopyrophosphate,** $Cu_2P_2S_7$, to be formed by heating cupric diphosphodisulphide with sulphur. L. Ferrand could not confirm this. J. J. Berzelius obtained **silver thiopyrophosphate,** $Ag_4P_2S_7$, by the method he used for the cupric salt; and L. Ferrand obtained it from its elementary components. According to J. J. Berzelius, the brownish or orange-yellow mass forms silver pyrophosphite (*q.v.*). L. Ferrand found that silver thiopyrophosphate is not attacked by boiling nitric acid, but it is completely decomposed by aqua regia. L. Ferrand obtained **zinc thiopyrophosphate,** $Zn_2P_2S_7$, from its elements. The pale yellow crystals are decomposed by water, and by acetic acid. He also prepared **cadmium thiopyrophosphate,** $Cd_2P_2S_7$, as a white, crystalline powder; it is rapidly decomposed by moist air; and only slightly attacked by hot nitric acid. L. Ferrand made **mercurous thiopyrophosphate,** $Hg_4P_2S_7$, as a red, crystalline powder which decomposes in moist air, and is attacked by hot nitric acid. J. J. Berzelius obtained **mercuric thiopyrophosphate,** $Hg_2P_2S_7$, by the method he used for the cupric salt; but L. Ferrand could not make it. White, needle-like crystals of **aluminium thiopyrophosphate,** $Al_2(P_2S_7)_3$, were obtained from the constituent elements. The product is unstable in moist air, and is decomposed by water, alkali-lye, and acids. Red, octahedral crystals of **lead thiopyrophosphate,** $Pb_2P_2S_7$, were obtained. The salt is fairly stable in moist air; decomposed by water; but is not attacked by cold nitric acid. The black, hexagonal lamellæ of **chromic thiopyrophosphate,** $Cr_2(P_2S_7)_3$, is very resistant towards nitric acid and aqua regia, but is decomposed by water, and moist air. The small, lustrous lamellæ of **ferrous thiopyrophosphate,** $Fe_2P_2S_7$, are insoluble in cold nitric acid. The deep brown crystals of **nickel thiopyrophosphate,** $Ni_2P_2S_7$, are decomposed by water and moist air, and attacked by nitric acid at 150°.

According to A. Stock, when lead or ammonium trithiophosphate is treated with anhydrous liquid hydrogen chloride, a yellow oil is obtained. Its composition corresponds with that of a mixture of thiophosphoric acids, or else with **pentathiopyrophosphoric acid,** $H_4P_2O_2S_5$. The m.p. is approximately $-55°$; and, at ordinary temp. it decomposes: $4H_4P_2O_2S_5=3P_2S_5+2H_3PO_4+5H_2S$. It reacts energetically with water with the deposition of sulphur. It is soluble in carbon disulphide. It reacts with dry ammonia, forming what appears to be **ammonium pentathiopyrophosphate.** According to A. Michaelis, when thiopyrophosphoryl tetrabromide is treated with water, sulphur, hydrogen sulphide, thiophosphoryl bromide, and **trithiopyrophosphoric acid,** $H_4P_2O_4S_3$, or $(HO)_4P_2S_3$, are formed. It is thought to have the constitution $(HO)_2{=}PS{-}S{-}SPS{=}(OH)_2$; and ethyl trithiophosphate was prepared. When the aq. soln. of the acid is treated with ammonium and a magnesium salt, no precipitate is formed in the cold, but when heated, a crystalline precipitate is deposited. The precipitate is soluble in acids, and the soln. soon gives off hydrogen sulphide and deposits sulphur. The aq. soln. of the acid gives a black precipitate with silver nitrate, and with lead acetate, white **lead trithiopyrophosphate** is probably formed which blackens when the soln. is boiled.

A. Stock found that light yellow **ammonium dithiometaphosphate,** $(NH_4S)POS$, or $(NH_4O)PS_2$, is formed when dry hydrogen sulphide acts on ammonium trithiophosphate at 175°. The salt is decomposed by water with the evolution of hydrogen sulphide.

§ 40. Phosphorus Sulphates

R. Weber[1] reported the complex $P_2O_5.3SO_3$ to be formed by the action of phosphorus pentoxide on sulphur trioxide, in the cold. It can be regarded as **phosphoryl sulphate,** $(PO)_2(SO_4)_3$, or as *sulphuryl phosphate,* $(SO_2)_3(PO_4)_2$. The white mass consists of transparent plates. It decomposes at 25°–30° with the evolution of sulphur trioxide. R. H. Adie added phosphoric acid very slowly to a cold mixture of sulphur trioxide and obtained a pale brown liquid with the composition $H_3PO_4.3SO_3$. This can be regarded as **phosphoryl hydrosulphide,** $PO(HSO_4)_3$. The compound fumes in air and is slowly decomposed by water, forming phosphoric and sulphuric acids.

C. Friedheim obtained complex salts crystallizing from aq. soln. of the components. Thus, with a mixture of $H_2SO_4 : 2NH_4(H_2PO_4)$, he obtained **ammonium sulphatophosphate,** $HO.PO(ONH_4).O.SO_2.ONH_4+H_2O$; and with the mixture $2KH_2PO_4 : H_2SO_4$, or $2H_3PO_4 : K_2SO_4$, he obtained **potassium sulphatophosphate,** $HO.PO(OK).O.SO_2.OK+H_2O$.

§ 41. Thiophosphoryl Halides, and Phosphorus Thiohalides

T. E. Thorpe and J. W. Rodger[1] prepared **thiophosphoryl fluoride,** PSF_3, by heating phosphorus tetritadecasulphide, or a mixture of phosphorus and sulphur, with an excess of lead fluoride: $3PbF_2+P_2S_5=3PbS+2PSF_3$, in a current of dry nitrogen in a leaden tube not over 250°, and collecting the gases over mercury; bismuth fluoride gives a similar result. They also obtained it by the action of arsenic trifluoride on thiophosphoryl chloride in a sealed tube at 150°: $AsF_3+PSCl_3=PSF_3+AsCl_3$; and C. Poulenc, by the action of sulphur, or antimony trisulphide on phosphorus trifluodichloride. At ordinary temp., thiophosphoryl fluoride is a transparent, colourless gas. The analysis and vap. density were found by T. E. Thorpe and J. W. Rodger to agree with the formula PSF_3. The gas condenses to a colourless liquid at 10–11 atm. press. At 3·8°, the gas liquefies at 7·6 atm. press.; at 10° and 9·4 atm. press.; at 13·8° and 10·3 atm. press.; and at 20·3° and 13 atm. press. When a tube of the gas is exhausted while electric sparks are passing, the spectrum consists of lines characteristic of the fluorine spectrum as seen in silicon fluoride and boron fluoride. After a time, as the press. is reduced, lines of phosphorus appear and entirely displace the fluorine spectrum. On further reducing the press., the phosphorus lines give place to a spectrum consisting entirely of sulphur flutings. Thiophosphoryl fluoride is therefore dissociated at the lowest temperature of the spark. The compound is decomposed by heat, forming sulphur, phosphorus, and phosphorus fluorides. The first action is considered to be: $PSF_3=PF_3+S$, and $5PF_3=3PF_5+2P$. A similar decomposition occurs when electric sparks are passed through the gas. If the decomposition be effected in a glass tube, at a sufficiently high temp., the gaseous product eventually consists entirely of silicon tetrafluoride. If a small quantity of mercury fulminate be exploded in the gas, a black deposit of mercuric sulphide is produced in quantity sufficient to show that all the sulphur is thrown out of combination. Thiophosphoryl fluoride is quickly decomposed by **air.** If a very slow stream of the pure gas be allowed to issue from a narrow platinum jet into the air, a white fume is instantly formed. No indication of flame is evident in daylight if the stream is sufficiently slow, but in the dark, the white fume is seen to be traversed in the vicinity of the jet by a blue, flickering flame. On increasing the current of the issuing gas the blue, flickering flame becomes more pronounced, and eventually travels back to the orifice of the jet, and ignites the stream. If the supply of gas is maintained, the gas continues to burn, giving off copious white fumes. The flame is greyish-green in colour, and is tipped with a faintly luminous, dull yellow portion, a light-blue zone occurring close to the platinum jet. If, instead of allowing the gas to issue from a jet, a considerable bulk be suddenly permitted to come in contact with the air, combination rapidly takes place, accompanied first of all by a beautiful blue flash of light followed by the greyish-green flame observed in the case of a jet of the gas. The shape of the flame indicates that the gas has spread itself for a considerable way over the surface of the mercury before combination ensues. If the layer of fume be allowed to rise above the top of the tube, the gas is no longer protected from the action of the air, and takes fire from above and burns with the greyish-green flame. When air is allowed rapidly to enter a gas-holder containing the gas, white fumes are at once formed, and these increase in quantity with the amount of air until, when a certain volume has been introduced, a sharp explosion takes place accompanied by light and heat, and the mercury is forcibly ejected from the cylinder. When a quantity of thiophosphoryl fluoride is passed into **oxygen** contained in a eudiometer standing over mercury, the fluoride, being about four times heavier than the oxygen, collects on the surface of the mercury, and burns quietly with a yellow flame, and a white fume is produced which quickly settles on the sides of the eudiometer. If the oxygen is passed into the gas, combination is more rapid, and a much denser deposit settles. When, however, the gas is gradually passed into the oxygen, that is, in a slow stream of small bubbles, the behaviour of the two gases is considerably altered. The first few bubbles on reaching the oxygen inflame, giving a blue flash of light. As oxidation products collect on the surface of the mercury, more bubbles may be added without any signs of combination until when a certain amount of gas has accumulated in the oxygen, a bright yellow flash is seen to traverse the gaseous mixture, and is followed by a smart detonation. Dry oxygen and thiophosphoryl fluoride may in fact exist together in presence of a sufficient quantity of oxidation products, apparently without interaction, provided all traces of moisture are carefully excluded from the mixture. The gas can be mixed with excess of dry oxygen without the slightest change taking place, even when the eudiometer is gently heated. The mixture, however, at once inflames on exposure to the air. That it is the moisture in the air which serves to start the reaction is proved by the fact that on passing fragments of blotting-paper moistened with water into the mixture of gas and oxygen their explosive union instantly follows. The reaction is not in accord with the equation: $2PSF_3+3O_2=2POF_3+2SO_2$; but a portion of the gas is acted on by oxygen: $PSF_3+O_2=PF_3+SO_2$; and the resulting trifluoride reacts with oxygen: $10PF_3+5O_2=6PF_5+2P_2O_5$, and $2PF_3+O_2=2POF_3$, so that the resultant equation is $10PSF_3+15O_2=6PF_5+2P_2O_5+10SO_2$. On introducing a flame of thiophosphoryl fluoride burning in air into an atmosphere of oxygen, the flame is reduced in size and becomes much more luminous. Its colour changes from greyish-green to bright yellow, and dense, white fumes are given off. The soln. of the products formed smells strongly of sulphur dioxide, and gives the reactions of phosphoric acid. Thiophosphoryl fluoride cannot be burned with safety from a jet in a closed apparatus through which a current of dry air or oxygen is passing. The flame is liable to be extinguished by a current of air or oxygen sufficiently powerful to carry over the products into the absorption-tubes. As a rule, the gas speedily relights itself, but not before sufficient unburnt gas has escaped to form a spontaneously explosive mixture. Two attempts were made to burn the gas in a closed space, and in each case the apparatus was shattered by explosion. These results illustrate the extreme instability of the gas and its low ignition temp. From the low ignition temp., and the ease with which the flame is extinguished, the temp. of the latter is very low. It is probably one of the coldest flames known. Our hands have frequently been surrounded by it without any too inconvenient sensation of heat. If a stream of thiophosphoryl fluoride is passed through **water,** comparatively little of the gas is absorbed. The bubbles rise to the surface, and take fire immediately on reaching the air, forming rings of white smoke. In order that any appreciable quantity may be dissolved, the gas must be shaken with the water for some time. The soln. is acid to test-paper, smells of hydrogen, and gives the reactions for phosphoric and hydrofluoric acids. The decomposition is in accordance with the equation: $PSF_3+4H_2O=H_2S+H_3PO_4+3HF$. If the soln. is effected in a vessel of flint-glass, the liquid at once becomes black, owing to the action of the hydrofluoric acid and hydrogen sulphide upon the lead silicate. The decomposition of thiophosphoryl fluoride by a soln. of **alkali hydroxide,** is analogous to that which C. A. Wurtz observed with thiophosphoryl chloride: $PSF_3+6NaOH=Na_3PSO_3+3NaF+3H_2O$. Thiophosphoryl fluoride has no action on **sulphuric acid.** If **ammonia** gas be passed into a confined vol. of thiophosphoryl fluoride, the two gases combine with the evolution of heat and the formation of a white solid. The volume ratios agree with the assumption that *thiophosphoryl diamidofluoride,* $P(NH_2)_2SF$, is formed: $PSF_3+4NH_3=2NH_4F+P(NH_2)_2SF$. Thiophosphoryl fluoride has no action on **carbon disulphide,** or **benzene**; it dissolves in **ether,** and the soln. burns with a greenish flame. Neither the gas nor the liquid has any appreciable action on dry **glass** at ordinary temp., but when heated with glass, a yellow film is deposited on the glass: $PSF_3=PF_3+S$, followed by $4PF_3+3SiO_2=3SiF_4+4P+3O_2$. A portion of the phosphorus combines with sulphur, whilst another part is oxidized and unites with the bases of the glass, forming pyrophosphates or metaphosphates. The deposit on the extreme upper part of the tube is yellow, and inflames on being heated in the air; it dissolves in water with separation of a little silica, and the soln. smells of sulphuretted hydrogen, and gives the reactions for phosphoric acid. If thiophosphoryl fluoride be passed over heated **sodium,** the metal takes fire and burns with a red flame, and the residual mass, when treated with water, gives off spontaneously inflammable phosphine. The gas has no action on **mercury.** The gas is completely absorbed by **lead dioxide.**

A number of compounds of phosphorus, sulphur, and chlorine have been reported, namely, the normal thiophosphoryl chloride, $PSCl_3$; **phosphorus dithiopentachloride,** PS_2Cl_5, reported by J. H. Gladstone,[2] and E. Baudrimont to be formed by melting a mixture of phosphorus pentachloride and sulphur, and fractionally distilling at 125°, the liquid remaining after the crystals of mixed phosphorus pentachloride and thiophosphoryl chloride have separated out. C. F. Gerhardt considered the product to be a mixture of thiophosphoryl chloride and sulphur monochloride, but E. Baudrimont could not separate it by fractional distillation. According to J. H. Gladstone, the pale yellow, mobile, refracting liquid is heavier than water. Its vap. density is 5·5, air unity. It evaporates at ordinary temp., boils at 118°, and does not freeze at —17°. It is affected by hydrogen at the b.p. of the liquid; it reacts slowly with water,forming hydrochloric, sulphuric, and phosphoric acids; it forms a dark red liquid with alkali-lye, and sulphur separates out. The liquid dissolves iodine, and sulphur. It dissolves hydrogen sulphide with the separation of sulphur; it is attacked by nitric acid; it dissolves phosphorus, and phosphorus pentachloride; it mixes with carbon disulphide; and it attacks alcohol, ether, and turpentine; it is also decomposed by metals—hot or cold.

H. Rose said that **phosphorus pentathiodichloride**, PS_5Cl_2, is formed by the action of phosphine on sulphur monochloride: $5S_2Cl_2+2PH_3=2PS_5Cl_2+6HCl$. The yellow, syrupy liquid is decomposed by water with the separation of sulphur and the evolution of hydrogen sulphide; and it is oxidized by nitric acid to sulphuric and phosphoric acids.

G. S. Sérullas[3] first made **thiophosphoryl chloride**, $PSCl_3$, by the action of hydrogen sulphide on phosphorus pentachloride: $PCl_5+H_2S=2HCl+PSCl_3$; L. Carius, B. Rathke, and A. W. Hofmann used carbon disulphide as the source of the sulphur: $CS_2+2PCl_5=CCl_4+2PSCl_3$; R. Weber, and T. E. Thorpe, phosphorus tetritadecasulphide; $P_4S_{10}+6PCl_5=10PSCl_3$, in a sealed tube at 150°; H. Schiff, potassium thiocyanate: J. Ponomareff, perthiocyanic acid; E. Baudrimont, sulphur, or antimony trisulphide: $3PCl_5+Sb_2S_3=2SbCl_3+3PSCl_3$; R. Weber, and E. Baudrimont, metal sulphides; A. Michaelis, thiophosphoryl bromide: $5PSBr_3+PCl_5=5PSCl_3+3PBr_5$; and C. F. Gerhardt, organic sulphur compounds. L. Henry made the compound by heating at about 130° in a sealed tube a mixture of a mol of phosphorus trichloride and a gram-atom of sulphur. A. Michaelis noted the formation of this compound when a mixture of phosphorus trichloride is heated with sulphur monochloride in a sealed tube at 160°—if thionyl chloride be employed some phosphoryl chloride is formed at the same time. F. Wöhler made it by heating sulphur monochloride with phosphorus: $2P+3S_2Cl_2=2PSCl_3+4S$. M. Chevrier added the phosphorus in small pieces at a time to the boiling sulphur monochloride, and the soln. of sulphur in thiophosphoryl chloride was fractionally distilled at 125°. A. von Flemming agitated the liquid with a little water before the rectification. T. E. Thorpe and A. E. H. Tutton heated sulphur monochloride with phosphorous oxide: $P_4O_6+6S_2Cl_2=2PSCl_3+2POCl_3+8S+2SO_2$; A. Besson, thionyl chloride and phosphine; H. Prinz, thionyl chloride and phosphorus tetritadecasulphide at 100°–150° in a sealed tube: $6SOCl_2+P_4S_{10}=4PSCl_3+3SO_2+9S$; L. Carius, phosphoryl chloride with phosphorus tetritadecasulphide, at 150°; and E. Baudrimont, thiophosphoryl bromide with chlorine, or by heating thiophosphoryl chlorodibromide or dichlorobromide: $2PSCl_2Br=PSCl_3+PSClBr_2$; E. Glatzel, by heating metal chlorides with phosphorus tetritadecasulphide: $3MCl+P_2S_5=M_3PS_4+PSCl_3$, and with ferric chloride: $6FeCl_3+2P_2S_5=3FeCl_2+3FeS_2+4PSCl_3$.

Analyses by G. S. Sérullas, L. Carius, and A. von Flemming are in agreement with the formula $PSCl_3$; and the vap. density determinations of A. Cahours, and M. Chevrier, 5·963 at 168°, and 5·878 at 298°, are in agreement with the same formula. The mol. wt. calculated from the b.p. of soln. of thiophosphoryl chloride in carbon tetrachloride is 209; and in benzene, 241; and from the f.p. of soln. in benzene, 160. The value calculated for $PSCl_3$ is 169·5, and for $(PSCl_3)_2$, 339. T. E. Thorpe said that the physical properties are in agreement with the assumption that the phosphorus is tervalent, and hence supposes the constitution to be $Cl_2P—S—Cl$; but W. Ramsay said that this evidence is of little weight—*vide* phosphoryl chloride. A. M. Wasilieff said that it can be regarded as a eutectic $P_2S_5+3PCl_5$, but the meaning of the term is not that usually employed.

G. S. Sérullas, E. Baudrimont, and L. Henry described thiophosphoryl chloride as a transparent, colourless, mobile liquid with a characteristic pungent and aromatic odour. The liquid fumes in air, and the smell of hydrogen sulphide indicates that it has been hydrolyzed by the moisture of the air. E. Baudrimont found the sp. gr. to be 1·631 at 22°; M. Chevrier, 1·636 at 22°; and T. E. Thorpe, 1·66816–1·66820 at 0° and 1·45599 at 125·12°. O. Masson, and J. A. Groshans studied the mol. vols.

of the family of halides. According to T. E. Thorpe, unit vol. of the liquid occupies v vols. at 0° when

	0°	20°	40°	60°	80°	100°	120°	125°
v . .	1·00000	1·02019	1·04129	1·06348	1·08695	1·11187	1·13842	1·14534

or $v=1+0{\cdot}0_3 99011\theta+0{\cdot}0_6 9030\theta^2+0{\cdot}0_8 3825\theta^3$. The mol. vol. at the b.p. is 116·34; and the at. vol. of the contained phosphorus is 52·4. G. S. Sérullas gave 125° for the b.p. of the liquid: L. Henry, 125°–126°; A. Cahours, 126°–127°; M. Chevrier, 124·5° at 750°; E. Baudrimont, 124·25°; T. E. Thorpe, 126° at 770 mm.; 125° and 125·12° at 760 mm. A. Besson found that the liquid freezes to a white solid when cooled in a bath of methyl chloride; he gave —35° for the m.p.; and added that the liquid is easily undercooled but it is readily crystallized by seeding with a crystal of thiophosphoryl dichlorobromide, or chlorodibromide. M. Chevrier gave 1·5593 for the refractive index of the liquid for Na-light. R. Weber found that the liquid is not decomposed by the electric current; and P. Walden gave 5·8 for the dielectric constant at 21·5°.

According to M. Chevrier, the vapour of thiophosphoryl chloride decomposes when passed through a red-hot tube, forming sulphur monochloride, phosphorus trichloride, and sulphur; and it is explosive when admixed with **oxygen.** G. S. Sérullas, and L. Henry observed that the liquid sinks in **water,** and is slowly decomposed in a few days, forming hydrochloric and phosphoric acids, hydrogen sulphide, and maybe a little sulphur which makes the soln. turbid. The liquid is decomposed in a few hours if it be agitated with water. G. Carrara and I. Zoppelari studied the speed of decomposition of the heterogeneous system, and represented the results by $\log \{a/(a-x)\}=Stak$, where S denotes the surface area of the two liquids in contact; a, the quantity of decomposable liquid; x, the amount of liquid decomposed at the time t; and k, a constant 0·0000132 at 10°, and 0·0000238 at 30°. E. Baudrimont found that it reacts with **chlorine,** forming sulphur monochloride and phosphorus pentachloride, and M. Chevrier represented the reaction: $PSCl_3+3Cl_2=SCl_4+PCl_5$; **iodine,** said C. A. Wurtz, does not react with thiophosphoryl chloride. According to A. Besson, dry **hydrogen bromide** does not react with boiling thiophosphoryl chloride; but when a mixture of the vapours is passed over pumice-stone at 400°–500°, a mixture of thiophosphoryl bromide, chlorodibromide, and dichlorobromide is formed; **hydrogen iodide** dissolves in liquid thiophosphoryl chloride at 0°, and the soln. darkens in colour owing to the reaction: $PSCl_3+5HI=PI_3+I_2+H_2S+3HCl$, and if the soln. be warmed phosphorus triiodide, phosphorus tetritahexa- and tetritadeca-sulphides, and phosphorus thiodiiodide are formed. G. S. Sérullas observed that hot liquid thiophosphoryl chloride dissolves **sulphur,** most of the solute separates out on cooling, and remains behind when the soln. is distilled. When a mixture of the vapour of thiophosphoryl chloride and **hydrogen sulphide** is passed through a red-hot tube, E. Baudrimont observed that hydrogen chloride, and phosphorus tetritadecasulphide are formed. When thiophosphoryl chloride is exposed to dry **ammonia** gas, heat is evolved, and a white solid is formed containing, according to E. Baudrimont, 30–40 per cent. of ammonia; or, according to J. H. Gladstone and J. D. Holmes, 60 per cent. J. H. Gladstone and J. D. Holmes represented the reaction as forming *thiophosphoryl diamidochloride*: $PSCl_3+4NH_3=2NH_4Cl+P(NH_2)_2ClS$; while H. Schiff, and M. Chevier assumed that thiophosphoryl triamide is formed: $PSCl_3+6NH_3=3NH_4Cl+PS(NH_2)_3$. G. S. Sérullas said that an aq. soln. of ammonia behaves like water, but J. H. Gladstone and J. D. Holmes said that ammonium monamidomonothiophosphate is formed; and, added M. Chevrier, if the ammonia is in excess, ammonium thiophosphate is produced. G. S. Sérullas found that **phosphorus** dissolves in warm thiophosphoryl chloride, but most of the solute separates out on cooling, and remains behind when the liquid is distilled; but F. Wöhler observed that when the liquid is distilled with phosphorus some phosphorus trichloride and sulphide are formed. A. Besson said that he was unable to prove the formation of phosphorus thiodiiodide when thiophosphoryl chloride is heated with **phosphonium iodide**; T. E. Thorpe and J. W. Rodger found that in a sealed tube at 150°, **arsenic trifluoride** forms thiophosphoryl fluoride (*q.v.*). According to E. Baudrimont, thiophosphoryl chloride dissolves **iodoform,** and mixes with **carbon disulphide.** S. Cloez found that thiophosphoryl chloride reacts vigorously with methyl or ethyl **alcohol**: $PSCl_3+3C_2H_5OH=(C_2H_5)H_2PSO_3+2C_2H_5Cl+HCl$, and slowly with amyl alcohol; it also reacts with **sodium ethoxide**: $3C_2H_5ONa+PSCl_3=(C_2H_5)_3PSO_3+3NaCl$.

Metals do not act on thiophosphoryl chloride in the cold. According to M. Chevrier, **sodium** and **potassium** are not attacked by boiling thiophosphoryl chloride, but if the chloride be dropped on the molten metal, the formation of alkali chloride, and sulphide, and sulphur is accompanied by an explosion; heated **mercury** forms mercuric chloride and a little phosphorus and sulphur. G. S. Sérullas said that alkali-lye acts like water; and, according to C. A. Wurtz, and S. Cloez, **sodium hydroxide** forms sodium monothiophosphate and sodium chloride, and, added M. Chevrier, some sulphur and sodium phosphate are produced; the last-named found that copper hydroxide acts in a similar manner, and that **silver oxide,** and red **mercuric oxide,** act when warmed, while yellow mercuric oxide acts in the cold. According to E. Baudrimont, **mercuric sulphide,** and **antimony trisulphide,** react at a red-heat, forming the corresponding chloride and thiophosphide. M. Chevrier found that **potassium permanganate** is decolorized with the separation of manganese dioxide; and T. E. Thorpe and S. Dyson represented the reaction with **silver nitrate**: $PSCl_3+4AgNO_3=Ag_3PO_4+AgCl+SO_2+2NOCl+N_2O_4$, and some pyrosulphuryl nitrate is formed.

Three thiophosphoryl bromides have been reported, $PSBr_3$, $P_2S_3Br_4$, P_2SBr_6, and PS_2Br, as well as the mixed chlorobromides, $PSBr_2Cl$, and $PSBrCl_2$. A. Stock[4] also reported that when dry hydrogen bromide acts on ammonium trithiophosphate some **thiophosphoryl hydrosulphodibromide,** $PSBr_2(SH)$, is formed, along with normal thiophosphoryl bromide. J. H. Gladstone first prepared **thiophosphoryl bromide,** $PSBr_3$, without recognizing its true nature. He obtained it by the action of hydrogen sulphide on phosphorus pentabromide, and E. Baudrimont showed that the reaction is that symbolized by $PBr_5+H_2S=PSBr_3+2HBr$. The product of this reaction, said R. W. E. MacIvor, is always mixed with some undecomposed pentabromide, which may be removed by washing the product with water at about 45°; and dried by pressure between bibulous paper, and finally in a desiccator over conc. sulphuric acid. A. Michaelis recommended removing the water by dissolving the product in carbon disulphide, dehydrating the soln. by calcium chloride, and evaporating the solvent from the clear, decanted liquor. E. Baudrimont obtained the same compound by the action of phosphorus pentabromide on heated antimony trisulphide; and by distilling a mixture of phosphorus tribromide with sulphur. The accompanying phosphorus bromide is removed by washing with warm water. A. Michaelis obtained it by the action of bromine on a soln. of eq. proportions of phosphorus and sulphur in carbon disulphide; by decomposing thiopyrophosphoryl bromide with water; and by heating hydrated thiophosphoryl bromide to its m.p. A. Besson obtained it by passing the vapour of thiophosphoryl chloride and hydrogen bromide over pumice-stone at 400°–500°, and by heating thiophosphoryl chlorodibromide. T. E. Thorpe proposed to prepare it by heating phosphorus pentabromide and tetritadecasulphide: $3PBr_5+P_2S_5=5PSBr_3$, as with the corresponding chloride. A. Stock obtained it, as indicated above, by treating ammonium trithiophosphate with anhydrous hydrogen bromide, digesting the yellow oil with water, and isolating the thiophosphoryl bromide by the carbon disulphide process just indicated. The analyses of A. Michaelis, E. Baudrimont, and A. Stock are in agreement with the formula $PSBr_3$.

E. Baudrimont described this compound as "a yellow, thick mass with a disgusting smell"; but A. Michaelis obtained it in octahedral crystals belonging to the cubic system by evaporation of the soln. in carbon disulphide, or phosphorus tribromide. A yellow, crystalline mass is obtained by cooling the molten compound, and it has a pungent, aromatic odour. The vapour attacks the eyes. E. Baudrimont gave 2·72 for the sp. gr.; A. Michaelis, 2·85 at 17°; and R. W. E. MacIvor, 2·87. For the m.p., E. Baudrimont gave 39°; A. Michaelis, and A. Stock, 38°; and R. W. E. MacIvor, 36·4°. The yellow liquid is readily undercooled. E. Baudrimont said that the liquid becomes brown when heated, and at 175°, a greenish vapour appears, and on distillation, phosphorus tribromide is first given off; this is followed by thiophosphoryl bromide at 212°–215°, while sulphur and phosphorus sulphide remain in the retort.

E. Baudrimont said that thiophosphoryl bromide fumes in **air,** but it does not burn in air. It is decomposed by **water,** forming hydrobromic and phosphoric acids, hydrogen sulphide, and sulphur. A. Michaelis, and R. W. E. MacIvor found that the reaction with water is very slow even when the water is boiling, and in addition to the products indicated by E. Baudrimont, some phosphorus acid is formed. For *hydrated thiophosphoryl bromide,* $PSBr_5H_2O$, *vide infra.* E. Baudrimont said that the thiobromide dissolves **sulphur,** and it is turbulently decomposed by conc. **nitric acid.** A. Michaelis found that thiophosphoryl bromide is slowly decomposed by **ammonia** in the cold, but rapidly when heated, forming sulphur, and ammonium sulphide, hydrophosphite, and phosphate. He represented the reaction with **phosphorus pentachloride :** $5PSBr_3+3PCl_5=5PSCl_3+3PBr_5$. The compound is soluble in **phosphorus trichloride,** and in **phosphorus tribromide ;** A. Michaelis, and R. W. E. MacIvor found that thiophosphoryl bromide dissolves in **ether,** and **carbon disulphide ;** and, added E. Baudrimont, in **chloroform.** It reacts when heated with **alcohol,** forming, according to A. Michaelis, ethyl thiophosphate, $PS(OC_2H_5)_3$. E. Baudrimont said that thiophosphoryl bromide is turbulently decomposed by **potassium hydroxide** soln.

A. Michaelis reported that when thiophosphoryl bromide is slowly distilled **thiopyrophosphoryl hexabromide,** P_2SBr_6, is formed. The same compound is formed by distilling thiopyrophosphoryl tetrabromide at 205°. It melts at —5°; and boils with decomposition at 205°. If this substance be stirred up with water, a yellow oil is formed which slowly crystallizes. It can be dried by press. between bibulous paper, and finally over conc. sulphuric acid and potassium hydroxide. The composition corresponds with hydrated thiopyrophosphoryl bromide, and it can be dehydrated by dissolving it in carbon disulphide, and agitation of the soln. with calcium chloride as indicated above. The yellow, crystalline mass has an aromatic smell. Its sp. gr. is 2·7937 at 18°, and it fuses at 35°. The water is gradually lost at the m.p. It does not fume in air, but after some days, it is gradually decomposed in air giving off hydrogen bromide.

According to A. Michaelis, **thiopyrophosphoryl tetrabromide,** $P_2S_3Br_4$, or $PSBr_2.S.PSBr_2$, is formed by gradually adding, with constant agitation, a carbon disulphide soln. of bromine to a well-cooled mixture of phosphorus tetritahexasulphide and the same menstruum. The solvent is distilled off at a temp. not exceeding 80°, and the last traces are removed by a current of dry carbon dioxide. The oily liquid is purified by dissolving it in ether, and distilling the solvent from the clear liquid. The pale yellow oil has a sp. gr. 2·2621 at 17°. It fumes in air, and then deposits sulphur. It has a pungent, aromatic odour. It cannot be distilled without decomposition into sulphur, phosphorus tetritadecasulphide, and thiopyrophosphoryl hexabromide. It is decomposed by water into sulphur, thiophosphoryl bromide, hydrogen sulphide, and phosphoric and thiophosphoric acids. Alkali-lye acts like water, only the reaction is more violent and no sulphur or thiophosphoryl bromide is formed; phosphorus pentabromide forms thiophosphoryl bromide; and alcohol forms $P_2S_3(OC_2H_5)_3Br$, $P_2S_3(OC_2H_5)_4$, and $P_2S_3(OC_2H_5)_2(SC_2H_5)_2$.

According to A. Michaelis, in the preparation of pyrophosphoryl tetrabromide, the crude product is extracted with ether, and there remains a yellow, viscid mass which can be dissolved in carbon disulphide. The solvent can be expelled from the filtered soln. by means of a current of carbon dioxide. The product is impure **thiometaphosphoryl bromide,** PS_2Br. It is decomposed by water, and reacts with alcohol, forming crystals of $P_2S_3(OC_2H_5)_2(SC_2H_5)_4$.

A. Besson[5] prepared **thiophosphoryl chlorodibromide,** $PSClBr_2$, along with the dichlorobromide and the normal bromide by passing a mixture of dry hydrogen bromide and thiophosphoryl chloride vapour over pumice-stone at 400°–500°, and separating the products by fractional distillation under reduced press. It is also obtained by heating thiophosphoryl dichlorobromide in a sealed tube at 100°: $2PSCl_2Br=PSClBr_2+PSCl_3$. The very pale green, fuming liquid has a sp. gr. 2·48 at 0°; and it forms a white solid with the m.p. —60°. It boils at 95° and 60 mm. press.; it slowly decomposes if heated at ordinary press.; and in a sealed tube at 100°, it decomposes into thiophosphoryl chloride, bromide, and dichlorobromide. It is slowly decomposed by water, and behaves towards other reagents like the dichlorobromide.

A. Michaelis prepared **thiophosphoryl dichlorobromide,** $PSCl_2Br$, by slowly adding bromine to ethyl thiophosphoryldichloride, $P(SC_2H_5)Cl_2$, in equimolar proportions: $P(SC_2H_5)Cl_2+Br_2=PSCl_2Br+C_2H_5Br$. The ethyl compound is obtained by adding mercaptan to phosphorus trichloride in equimolar proportions, and collecting the fraction boiling at 172°–175°. The crude dichlorobromide was shaken with water so long as a perceptible action occurs, dried by calcium chloride, and freed from dissolved hydrochloric and hydrobromic acids by gently warming. A. Besson obtained it as indicated above, and also by heating thiophosphoryl chlorodibromide in a sealed tube at 100°, and isolating the desired product by fractional distillation. A. Besson, and A. Michaelis said that the pale yellow or colourless liquid smells like thiophosphoryl chloride. A. Besson gave 2·12 for the sp. gr. at 0°; and when cooled, it forms a white solid melting at —30°. The liquid is readily undercooled, and the surfused liquid readily crystallizes when seeded with a crystal of thiophosphoryl dichlorobromide or chlorodibromide. A. Michaelis found that the liquid cannot be distilled at atm. press. without decomposition; A. Besson said that it decomposes at 100° in a sealed tube: $2PSCl_2Br=PSCl_3+PSClBr_2$, but he was able to distil the liquid at 80° and 60 mm. press. A. Michaelis said that the compound is acted upon by water only with difficulty, and may even be partially distilled in a current of steam. Its complete decomposition is effected only by heating in sealed tubes to 150°. The products are sulphur, hydrogen sulphide, phosphorus, phosphoric, hydrochloric, and hydrobromic acids. Only half as much sulphur, however, is obtained as in the analogous decomposition of $PSBr_3$ by water. A. Besson added that the dichlorobromide is boiled at about 80° under a press. of 6 mm.; sp. gr.=2·12 at 0°. When strongly cooled, it forms a white solid, which melts at 30°. It decomposes slowly in presence of water, more rapidly in contact with soln. of alkalies. Fuming nitric acid oxidizes it violently, but the acid at 36° acts more slowly, and completely oxidizes the sulphur and phosphorus. When heated at 100°, it decomposes into the thiophosphoryl trichloride and the chlorodibromide, the latter, in its turn, decomposing and yielding, amongst other products, thiophosphoryl tribromide.

A number of **phosphorus thioiodides** have been reported: P_2SI_2, $P_2S_2I_2$, P_2SI_4, and $P_4S_3I_2$; but their individuality is not well-established. The subject needs revision. Another compound was prepared by V. Auger[6] by mixing carbon disulphide soln. of phosphorus triiodide and sulphur. The reddish-brown crystals were stated by M. Demassieux to be rhombohedral. They were not obtained pure enough for analysis, but by analogy with the corresponding compounds of arsenic and antimony triiodides, their composition is $PI_3.3S_8$, or **phosphorus tetracosithiotriiodide.**

According to A. Besson, hydrogen iodide dissolves without change in thiophosphoryl chloride cooled in a mixture of ice and salt, but at 0° hydrogen chloride and hydrogen sulphide are given off, and the liquid contains free iodine and phosphorus triiodide, the action being analogous to that of hydrogen iodide on phosphorus oxychloride. In sealed tubes at temperatures above 0°, the reaction is more complex, and the products depend on the temperature. In all cases, iodine is liberated, hydrogen chloride and sulphur are given off, and the liquid contains phosphorus triiodide and a mixture of phosphorus trisulphide and pentasulphide in varying proportions, together with small quantities of **phosphorus thiodiiodide,** P_2SI_2, an orange solid, which melts at about 75°, and is very soluble in carbon disulphide. The thioiodide does not sublime in a vacuum, decomposes when exposed to air, and readily when heated. In order that it may be formed in appreciable quantity, the soln. of hydrogen iodide in the thiophosphoryl chloride must not be heated above 30°–40°.

E. Drechsel reported a product with the empirical formula PSI to be formed by the action of carbon disulphide on phosphonium iodide: $3CS_2+4PH_4I=3PSI+P(CH_3)_3.HI+3H_2S$; and L. Ouvrard showed that while dry hydrogen sulphide has no action on phosphorus triiodide at ordinary temp., **phosphorus dithiodiiodide,** $P_2S_2I_2$, is produced when the dry gas is passed over the molten iodide: $2PI_3+2H_2S=P_2S_2I_2+4HI$. The same compound is produced when the required proportions of the three elements in carbon disulphide soln. are heated in the absence of air, and the solvent evaporated; by heating the triiodide with phosphorus tetritahexasulphide in an inert gas: $2P_2S_3+2PI_3=3P_2S_2I_2$; and by the action of iodine on a soln. of the same sulphide in carbon disulphide: $2P_2S_3+3I_2=S_2I_2+2P_2S_2I_2$. The red, prismatic crystals are readily decomposed in air with the formation of hydrogen iodide; they inflame when heated in air, burn to sulphur dioxide, iodine, etc.; they are decomposed by water into hydriodic and phosphoric acids, and phosphorus tetritahexasulphide which, in turn, is resolved into phosphoric acid, hydrogen sulphide, etc. The dithiodiiodide is readily dissolved by carbon disulphide.

L. Ouvrard said that when an excess of phosphorus triiodide acts on phosphorus tetritahexasulphide, **phosphorus thiotetraiodide,** P_2SI_4, is formed: $P_2S_3+4PI_3=3P_2SI_4$. It is readily decomposed on recrystallization from carbon disulphide: $3P_2SI_4=P_2S_3+4PI_3$, and appears to be more stable in soln. L. Ouvrard also reported **phosphorus trithiodiiodide,** $P_4S_3I_2$, to be formed by the action of dry hydrogen sulphide on phosphorus diiodide at 110°–120°: $2P_2I_4+3H_2S=6HI+P_4S_3I_2$, until no more hydrogen iodide is given off. The reaction is very slow, and occupies 40–50 hrs. The product is extracted with carbon disulphide, and the filtered soln. evaporated in a current of carbon dioxide. The same compound is formed when the correct proportions of the three elements are dissolved in carbon disulphide, and after the evaporation of the solvent, heating the product to 120° in a current of an inert gas. It is also formed when the correct proportion of iodine is dissolved in a carbon disulphide soln. of phosphorus tetritatrisulphide. L. Wolter added that no other phosphorus sulphide yields a well-defined iodide under these conditions, and he recommended the reaction as a test for the tetritatrisulphide in match composition. L. Wolter described the trithiodiiodide as crystallizing from carbon disulphide in orange-yellow, silky needles; and L. Ouvrard, as highly refractive, golden-yellow prisms belonging to the triclinic system. L. Wolter gave 119·5° for the m.p.; and L. Ouvrard said that when heated in air, the trithiodiiodide melts at about 106° to a viscous liquid which easily remains in a state of surfusion, and at about 300°, it burns, forming phosphorus pentoxide, sulphur dioxide, and iodine; and at 300° in vacuo, it forms iodine and phosphorus tetritatrisulphide. It is stable in dry air, and can be preserved for a long time in a closed vessel; it is slowly decomposed by moist air with the evolution of hydrogen sulphide. Cold water has very little effect on it, but it is rapidly decomposed by boiling water. Fuming nitric acid attacks it with explosive violence and the evolution of light. It dissolves readily in carbon disulphide, and is only slightly soluble in benzene, xylene, toluene, chloroform, ligroin, and acetic acid. It is still less soluble in absolute alcohol and ether. The soln. in hot ether yield crystals of the same compound on cooling.
